Abstract
Carbon acquisition in relation to CO₂ supply was investigated in three marine bloom-forming microalgae, the diatom Skeletonema costatum, the flagellate Phaeocystis globosa, and the coccolithophorid Emiliania huxleyi. In vivo activities of extracellular (eCA) and intracellular (iCA) carbonic anhydrase activity, photosynthetic O₂ evolution, CO₂ and HCO₃⁻ uptake rates were measured by membrane inlet mass spectrometry in cells acclimated to pCO₂ levels of 36, 180, 360, and 1,800 ppmv. Large differences were obtained between species both with regard to the efficiency and regulation of carbon acquisition. While eCA activity increased with decreasing CO₂ concentration in S. costatum and P. globosa, consistently low values were obtained for E. huxleyi. No clear trends with pCO₂ were observed in iCA activity for any of the species tested. Half saturation concentrations (K₁/₂) for photosynthetic O₂ evolution, which were highest for E. huxleyi and lowest for S. costatum, generally decreased with decreasing CO₂ concentration. In contrast, K₁/₂ values for P. globosa remained unaffected by pCO₂ of the incubation. CO₂ and HCO₃⁻ uptake were taken up simultaneously by all species. The relative contribution of HCO₃⁻ to total carbon uptake generally increased with decreasing CO₂, yet strongly differed between species. Whereas K₁/₂ for CO₂ and HCO₃⁻ uptake were lowest for S. costatum and E. huxleyi, it did not change as a function of pCO₂ in P. globosa. The observed taxon-specific differences in CO₂ sensitivity, if representative for the natural environment, suggest that changes in CO₂ availability may influence phytoplankton species succession and distribution. By modifying the relative contribution of different functional groups, e.g., diatomaceous versus calcareous phytoplankton, to the overall primary production this could potentially affect marine biogeochemical cycling and air–sea gas exchange.

Marine phytoplankton account for approximately 50% of global primary production (Falkowski et al. 1998). Changes in the oceanic primary production over geological timescales have influenced biogeochemical cycles and thus atmospheric pCO₂ levels. Of the approximately 20,000 phytoplankton species (Falkowski and Raven 1997), however, only a relatively small number of key species control the cycling of carbon and other bioelements. Among these, bloom-forming phytoplankton play a major role in determining vertical fluxes of particulate material. With respect to their specific effects on biogeochemical cycling, phytoplankton can be separated into so-called functional groups (Falkowski et al. 1998), such as silicifying and calcifying phytoplankton, flagellates, and N₂-fixating cyanobacteria. The relative contribution of each of these groups to marine primary production largely determines biogeochemical cycling in the ocean and the interplay between the various bioelements. What determines the distribution and succession of phytoplankton in space and time, especially with respect to the different functional groups, remains one of the central but still unresolved questions in biological oceanography.

Until recently, the potential role of inorganic carbon acquisition in marine phytoplankton ecology and evolution has largely been ignored, particularly since dissolved inorganic carbon in seawater is always in excess relative to other plant nutrients. The primary carboxylating enzyme, Ribulose-1,5-bisphosphate carboxylase/oxygenase (RubisCO), however, is restricted to CO₂ for carbon fixation. Owing to the low concentrations of aqueous CO₂ present in seawater (5–25 µmol L⁻¹) and the poor substrate affinity of RubisCO for CO₂ (K₅ of 20–70 µmol L⁻¹, Badger et al. 1998) photosynthesis of phytoplankton may suffer from CO₂ limitation. To overcome the low CO₂ affinity of their main carboxylating enzyme, most microalgae have developed mechanisms to enhance their intracellular CO₂ concentration relative to external concentrations. These CO₂ concentrating mechanisms (CCMs) comprise active uptake of CO₂ and/or HCO₃⁻ into the algal cell and/or the chloroplast (e.g., Amoroso et al. 1998). The enzyme carbonic anhydrase (CA), which accelerates the otherwise slow rate of conversion between HCO₃⁻ and CO₂, is also involved in most CCMs. Significant differences in the catalytic efficiency of RubisCO exist between major algal and cyanobacterial taxa (Badger et al. 1998). These taxonomic differences seem to be reflected in the efficiency of their CCMs, i.e., with decreasing CO₂ affinity of RubisCO the capacity of cells to concentrate inorganic carbon increases (Tortell 2000). Raven (1997) suggested that differences in inorganic carbon acquisition could also impose other resource requirements. After all, differences in the efficiency

We would like to thank Dr. Gabi Amoroso, Dominik Müller, and Christoph Thyssen for technical support and laboratory assistance and Aaron Kaplan for his constructive comments on the manuscript. This work was supported by the Netherlands-Bremen Cooperation in Oceanography (NEBROC) and by the German–Israeli Cooperation in Marine Sciences (Mars 2/3), which is funded by the German Federal Ministry of Education and Research (BMBF).
and regulation of carbon acquisition between phytoplankton species as well as taxonomic groups may well affect their relative fitness in a resource-limited environment.

In the present study we investigated the changes in carbon acquisition of marine microalgae in response to changes in CO₂ supply. Our test organisms, the diatom Skeletonema costatum, the flagellate Phaeocystis globosa, and the coccolithophorid Emiliania huxleyi, representatives of three phytoplankton functional groups, are all bloom forming and have a worldwide distribution. In each of these species we examined photosynthetic O₂ evolution and quantified CO₂ and HCO₃⁻ fluxes across the plasmalemma during steady-state photosynthesis by the use of membrane inlet mass spectrometry (Badger et al. 1994). Moreover, activities of extracellular and intracellular CA were determined by monitoring ¹⁸O exchange from doubly labeled ¹³C¹⁸O₂ (Palmqvist et al. 1994). The results of this study are discussed with respect to the considerable variability in CO₂ availability, both on glacial–interglacial time scales and in view of the present rise in atmospheric pCO₂. A better understanding of the mechanisms determining the efficiency and regulation of carbon acquisition may help to improve our ability to predict the responses of marine phytoplankton to future environmental changes.

Material and methods

Culture conditions and sampling—Skeletonema costatum, Phaeocystis globosa (both strains collected in the North Sea and maintained in stock culture for some years), and a calcifying strain of Emiliania huxleyi (B92/11) were grown at 15°C in 0.2-µm-filtered and unbuffered seawater (salinity 32), which was enriched with nutrients according to f/2 medium (Guillard and Ryther 1962). Batch cultures were grown in 1-liter glass tubes under continuous light and an incident photon flux density (PFD) of 180 µmol photons m⁻² s⁻¹. Air containing CO₂ partial pressures (pCO₂) of 36, 180, 360, and 1,800 ppmv was sparged continuously through the cultures, to the considerable variability in CO₂ availability, both on glacial–interglacial time scales and in view of the present rise in atmospheric pCO₂. A better understanding of the mechanisms determining the efficiency and regulation of carbon acquisition may help to improve our ability to predict the responses of marine phytoplankton to future environmental changes.

Determination of CA activity—CA activity was determined from the ¹⁸O depletion of doubly labeled ¹³C¹⁸O₂ in water caused by several hydration and dehydration steps of CO₂ and HCO₃⁻ [Silverman 1982]. This mass spectrometric procedure allows the determination of CA activity from intact cells under conditions similar to those during growth and differentiates between extracellular CA (eCA) and intracellular CA (iCA) activity (Silverman 1982; Burkhardt et al. 2001). All measurements were carried out in an 8-ml thermostated cuvette, which was attached to a quadrupole mass spectrometer (MSD 5970; Hewlett Packard) via a semipermeable membrane inlet system. Changes in the concentrations of the CO₂ isotopes ¹³C¹⁸O¹⁸O (m/z = 49), ¹³C¹⁴O¹⁸O (m/z = 47) and ¹³C¹⁸O²O (m/z = 45) were recorded continuously and calculated as

\[
¹⁸O \log(\text{enrichment}) = \log \frac{(¹³C¹⁴O₂) \times 100}{¹³C²O₂} = \log \frac{(49) \times 100}{45 + 47 + 49}
\]

Measurements of eCA and iCA activities were performed in CO₂-free f/2 medium buffered with 50 mmol L⁻¹ HEPES (pH 8.0) at 15°C. If not stated otherwise, all assays were carried out in the dark. 1 mmol L⁻¹ NaH¹³CO₃ was added and the uncatalyzed rate of ¹⁸O loss was recorded for about 8 min followed by the addition of 50–150 µl of the resuspended cells to yield a final Chl a concentration of 0.4–3 µg ml⁻¹. Examples for the change in log (enrichment) upon the addition of algal cells to the cuvette in the dark are given in Fig. 1. For calculation of eCA activity, the linear decrease in ¹⁸O atom fraction after the addition of the sample (S₁) was compared to the noncatalyzed decline (S₀) and normalized on a Chl a basis (Badger and Price 1989):

\[
U = \frac{(S₂ - S₁) \times 100}{S₁ \times \text{mg Chl a}}
\]

iCA activity was estimated from the rapid decline in log (enrichment) upon the injection of cells and calculated according to Palmqvist et al. (1994). In the latter experiments a dextran-bound sulfonamide (DBS; Synthelec AB), an inhibitor of eCA, was added prior to the injection of cells to a final concentration of 100 µmol L⁻¹. In the presence of DBS the final slope equals the initial slope (S₁ = S₂), indicating a complete inhibition of external CA.

Subsequent to the iCA measurements, light was switched on (300 µmol photons m⁻² s⁻¹) for 3 min. Light-induced changes in the ¹⁸O exchange can be indicative for active transport of Ci since there will be an enhanced influx of CO₂ and HCO₃⁻ into the cell to the active site of iCA, resulting in an increase of the ¹⁸O loss (Badger and Price 1989).
C acquisition of marine phytoplankton

Fig. 1. Changes in the $^{18}$O log (enrichment) of doubly labeled $^{13}$C$^{18}$O$_2$ for in vivo measurements of (a) eCA and (b) iCA activities. In both experiments the initial linear decline in log(enrichment) ($S_1$) represents the uncatalyzed rate of $^{18}$O exchange. (a) A higher final linear rate of $^{18}$O depletion ($S_2$) is indicative for the presence of eCA activity, which is calculated according to Eq. 2. (b) Intracellular CA activities were determined in the presence of 100 $\mu$mol L$^{-1}$ DBS. The drop ($\Delta$) in the log (enrichment) was determined by extrapolating the final slope ($S_2$) back to the addition of the cells. The data show measurements for $P$. globosa acclimated to 36 ppmv CO$_2$. For direct comparison the same amount of cells (Chl $a$ concentration 0.45 $\mu$gm L$^{-1}$) from the same culture was added in these assays.

Fig. 2. Chl $a$–specific activities of (a) eCA and (b) iCA for $S$. costatum, $P$. globosa, and $E$. huxleyi as a function of pCO$_2$ in the culture medium. Values represent the mean of at least three independent measurements ($\pm$SD).

Effect of eCA on net photosynthesis—To investigate the potential effect of eCA on net photosynthesis, O$_2$ evolution was monitored in the absence and presence of DBS (100 $\mu$mol L$^{-1}$). The measurements were performed with cells acclimated to 360 and 180 ppmv CO$_2$ at concentrations of 3 and 27 $\mu$mol CO$_2$ L$^{-1}$. The assay conditions were the same as for the carbon flux measurements (see below).

Determination of net photosynthesis, CO$_2$ and HCO$_3^-$ uptake—To investigate inorganic carbon fluxes during steady-state photosynthesis, the same membrane inlet system was used as for the CA measurements. The method established by Badger et al. (1994) is based on simultaneous measurements of O$_2$ and CO$_2$ during consecutive light and dark intervals. It has been applied in several studies of cyanobacteria and freshwater microalgae (Palmqvist et al. 1994; Tchernov et al. 1997; Amoroso et al. 1998) and recently also of marine diatoms (Burkhardt et al. 2001).

In the present study we followed largely the protocol described by Burkhardt et al. (2001). All measurements were performed in f/2 medium, buffered with 50 mmol L$^{-1}$ HEPES (pH 8.0) at 15$^\circ$C. DBS concentration in the cuvette was 100 $\mu$mol L$^{-1}$. Chl $a$ concentration ranged between 1 and 3 $\mu$gm L$^{-1}$. Light and dark intervals during the assay lasted 6 and 7 min, respectively. The incident photon flux density was 300 $\mu$mol m$^{-2}$ s$^{-1}$. For further details on the method and calculation we refer to Badger et al. (1994) and Burkhardt et al. (2001).

Results

CA activity—Determination of carbonic anhydrase (CA) activity using membrane inlet mass spectrometry distinguishes between extracellular (eCA) and intracellular (iCA) activity, yet the obtained values are of different denotation. Values for eCA activity are a direct measure for the acceleration in the rate of conversion between CO$_2$ and HCO$_3^-$ (Fig. 1a) and thus can be used for the comparison of species and different treatments. In $S$. costatum, we observed an almost 60-fold increase in Chl $a$–specific activity of eCA with decreasing CO$_2$ concentrations (Fig. 2a). The eCA activity in $P$. globosa remained high in all incubations and increased only about twofold from 180 to 36 pCO$_2$, whereas eCA activity in $E$. huxleyi was low and remained unaffected by pCO$_2$ in the incubation.

Determination of iCA activity ($\Delta$) in this approach is dependent on the rate of diffusive CO$_2$ entry into the cell and the rate of intracellular and extracellular $^{18}$O depletion (Fig. 1b). Owing to the presence of DBS, the influence of eCA activity was excluded. Factors influencing the diffusive properties of the membranes, such as cell size and shape or intracellular pH potentially affect estimates of iCA activity. Thus $\Delta$ values have arbitrary units, which allows the comparison of iCA activities between treatments but not between species. All species tested contained intracellular CA regardless of the growth conditions. The activity of iCA in $P$. globosa and $E$. huxleyi showed no trend with CO$_2$ in the incubation (Fig. 2b). In contrast, a two to threefold higher
Table 1. Effect of DBS on net photosynthesis expressed as percentage change in the rate upon the addition of 100 μmol L⁻¹ DBS. Cells were acclimated to 360 and 180 ppmv CO₂ and tested at CO₂ concentration of 3 and 27 μmol L⁻¹ (pH 8.0). Data represent the mean values of three independent measurements (±SD). enzyme activity was observed in cells of S. costatum grown at 36 pCO₂ compared to cells grown at higher pCO₂ levels.

To test the effect of eCA on photosynthesis in cells acclimated to 180 and 360 ppmv CO₂, we monitored the O₂ evolution prior to and after the addition of DBS (100 μmol L⁻¹) at CO₂ concentrations of 3 and 27 μmol L⁻¹. At the high CO₂ concentration DBS did not inhibit net photosynthesis in any of the investigated species (Table 1; Fig. 3). At the low CO₂ concentration, net photosynthesis of S. costatum was inhibited by 47% and 58% in 360 and 180 ppmv acclimated cells, respectively. For P. globosa the inhibition of net photosynthesis at the low CO₂ concentration was 6% for 360 ppmv acclimated cells and increased to 19% (180 ppmv acclimated cells). In E. huxleyi no inhibition of net photosynthesis by DBS was found.

The ³¹O exchange technique also indicates the presence of light-dependent Ci transport systems. As shown in Fig. 4, illumination of 1,800 ppmv CO₂ grown cells of S. costatum and P. globosa resulted in a rapid uptake of ³¹O-labeled ¹³CO₂ (m/z = 49 and 47) and a large efflux of unlabeled ¹³CO₂, (m/z = 45). This leads to a light-dependent decrease in log (enrichment) in both algae. In contrast, in E. huxleyi this light-stimulated decline in log (enrichment) was only observed in cells acclimated to 360 ppmv CO₂ and below.

Photosynthesis, CO₂ uptake, and HCO₃⁻ uptake—Net photosynthesis was measured by monitoring the O₂ evolution over several light–dark intervals with increasing Ci concentrations at constant pH. Simultaneous measurements of the
CO₂ concentration enabled us to estimate gross CO₂ uptake and HCO₃⁻ uptake kinetics according to equations by Badger et al. (1994). Net photosynthesis, gross CO₂ uptake, and HCO₃⁻ uptake are shown as a function of CO₂ and/or HCO₃⁻ concentration for *S. costatum*, *P. globosa*, and *E. huxleyi* (Figs. 5–7) acclimated to different pCO₂ levels. The corresponding kinetic parameters such as \( K_{1/2} \) values and maximum rates (\( V_{\text{max}} \)) are summarized in Table 2. All species were able to take up both CO₂ and HCO₃⁻ during steady-state photosynthesis. However, large species-specific differences in the efficiency and regulation of carbon acquisition and photosynthesis are apparent.

In *S. costatum* \( K_{1/2} \) values for photosynthetic O₂ evolution decreased from 2.7 to 0.3 \( \mu \text{mol L}^{-1} \) CO₂ (505 to 17 \( \mu \text{mol L}^{-1} \) HCO₃⁻) with decreasing pCO₂ in the incubation, while \( V_{\text{max}} \) was unaffected by pCO₂ (Fig. 5; Table 2). The \( K_{1/2} \) of gross CO₂ uptake decreased from 3.2 to 0.4 \( \mu \text{mol L}^{-1} \) CO₂ with decreasing pCO₂, and \( V_{\text{max}} \) remained relatively constant. The \( K_{1/2} \) of HCO₃⁻ uptake decreased to 5 \( \mu \text{mol L}^{-1} \) HCO₃⁻, and \( V_{\text{max}} \) strongly increased with decreasing pCO₂ in the incubation (48 to 239 \( \mu \text{mol L}^{-1} \) mg Chl a \(^{-1} \) h \(^{-1} \)). In *P. globosa* \( K_{1/2} \) values for photosynthetic O₂ evolution showed no consistent trend with pCO₂ and varied between 1.5 and 2.4 \( \mu \text{mol L}^{-1} \) CO₂ (122–175 \( \mu \text{mol L}^{-1} \) HCO₃⁻), while the \( V_{\text{max}} \) increased slightly with decreasing pCO₂ in the incubation (Fig. 6; Table 2). The \( K_{1/2} \) and \( V_{\text{max}} \) of gross CO₂ uptake remained unaffected by pCO₂ in the incubation, with \( K_{1/2} \) showing values between 1.6 and 2.3 \( \mu \text{mol L}^{-1} \) CO₂. Likewise, HCO₃⁻ uptake kinetics did not change between the different pCO₂ incubation, except for a somewhat higher \( V_{\text{max}} \) at 36 ppmv pCO₂. In *E. huxleyi* \( K_{1/2} \) values for photosynthetic O₂ evolution were much higher than of the other two species and decreased from 27.3 to 9.6 \( \mu \text{mol L}^{-1} \) CO₂ (1,646 to 581 \( \mu \text{mol L}^{-1} \) HCO₃⁻) with decreasing pCO₂ in the incubation (Fig. 7; Table 2). The \( V_{\text{max}} \) of O₂ evolution was unaffected by pCO₂. For gross CO₂ uptake the \( K_{1/2} \) decreased from 13.4 to 4.6 \( \mu \text{mol L}^{-1} \) CO₂ with decreasing pCO₂, while \( V_{\text{max}} \) remained relatively constant. The HCO₃⁻ uptake kinetics did not follow a Michaelis–Menten kinetic, but the HCO₃⁻ uptake rates relative to O₂ evolution slightly increased with decreasing pCO₂ in the incubation.

**Discussion**

In this study we investigated several aspects of inorganic carbon acquisition in ecologically relevant phytoplankton species by means of membrane inlet mass spectrometry. Acclimation to different pCO₂ levels was performed in unbuffered seawater with fairly low cell densities to match the natural environment as much as possible. The apparent \( K_{1/2} \) values for photosynthetic O₂ evolution were significantly lower than values known for RubisCO (Badger et al. 1998), indicating the operation of a CCM. Moreover, all three species were able to use both CO₂ and HCO₃⁻ independently of the CO₂ concentration provided during growth. Despite these similarities, large differences in the efficiency and regulation of carbon acquisition become evident between species.

*Carbonic anhydrase activity*—Extracellular CA, which accelerates the conversion of HCO₃⁻ to CO₂ at the cell surface (Sültemeyer 1998), was found to increase in response to diminishing CO₂ supply in many microalgae, underlining the importance of eCA in carbon acquisition (e.g., Nimer et al. 1997; Elzenga et al. 2000; Burkhardt et al. 2001). The mass spectrometric measurement of eCA activity used in this study has the advantage that highly reproducible results can be obtained from living cells under growth temperature. Since eCA is the only CA that has access to all labeled Ci species in darkness, values for eCA activity indicate the acceleration in the rate by which the isotopic equilibrium is achieved and thus for changes in the rate of conversion between CO₂ and HCO₃⁻.

In the present study *S. costatum* showed the strongest regulation and highest activity of eCA (Fig. 2). At 1,800 ppmv CO₂ activities of eCA were close to the detection limit but strongly increased with decreasing pCO₂ in the incubation. These results are consistent with the pH-dependent trends in eCA activity for *S. costatum* observed in other studies (Nimer et al. 1997, 1998). Potential light activation of eCA, as has been shown by Nimer et al. (1998), is not accounted for in our assay. For *S. costatum* they observed an increase in eCA activity at low CO₂ concentrations in the light compared to darkness, which was associated with higher redox activity of the plasma membrane. According to their findings the eCA activity obtained in our study could be higher at low CO₂ concentrations during illumination, which would potentially increase changes in eCA activity over the investigated [CO₂] range. For *P. globosa* we obtained high and relatively constant activities for eCA, indicating a constitutive rather than regulated system (Fig. 2). Elzenga et al. (2000) investigated the role of eCA in inorganic carbon use for *P. globosa* and found a gradual induction of eCA activity with decreasing CO₂ concentration over the duration of a bloom. Strain-specific differences in eCA activity, as known for example for *Phaeodactylum tricornutum* (John-McKay and Colman 1997; Burkhardt et al. 2001) or differences in carbon acquisition between single-celled flagellates (used in this study) and colonies of *P. globosa*, could be reasons for these apparent discrepancies. The eCA activities in *E. huxleyi* were very low and did not change with pCO₂ of the incubation (Fig. 2). Using an isotope disequilibrium method, Elzenga et al. (2000) could not detect any eCA activity for this strain of *E. huxleyi*. Nimer et al. (1994) investigated eCA activities of another high-calcifying strain by an electrochemical method. They could not detect any eCA activity until *E. huxleyi* had reached the stationary phase. In contrast to the apparent role of eCA in carbon acquisition of *S. costatum* and *P. globosa*, eCA seems to play a minor role, if any, in this strain of *E. huxleyi*.

To further investigate a possible function of eCA on photosynthesis, we monitored O₂ evolution in the presence and absence of the CA inhibitor DBS at low (3 \( \mu \text{mol L}^{-1} \)) and high (27 \( \mu \text{mol L}^{-1} \)) CO₂ concentrations (Table 1, Fig. 4). DBS has previously been reported not to penetrate into the cells and, therefore, should inhibit only eCA activity. At 3 \( \mu \text{mol L}^{-1} \) CO₂, addition of DBS caused a strong reduction of O₂ evolution in 180 ppmv CO₂ acclimated cells of *S. costatum*. No such inhibitory effect of DBS on O₂ evolution was observed when photosynthesis was measured under 27 \( \mu \text{mol L}^{-1} \) CO₂ (Fig. 4). Similar results were obtained for
360 ppmv CO₂ grown cells of *S. costatum.* In contrast, in *P. globosa* significant DBS inhibition only occurred in 180 ppmv CO₂ acclimated cells (Table 1). In *E. huxleyi* addition of DBS had no effect on O₂ production (Table 1), which is consistent with the low eCA activities for this strain. The observed inhibition of O₂ evolution for *S. costatum* and *P. globosa* underlines the important role of eCA in carbon acquisition and supports earlier conclusions that eCA is essential for reaching maximum rates of photosynthesis under at least subsaturating CO₂ concentrations (SuÈltemeyer et al. 1990).

It is a common notion that eCA increases the CO₂ concentration at the plasma membrane and herewith favors CO₂ uptake. This only holds true, however, if low CO₂ concentrations in the boundary layer are the consequence of a disequilibrium in the carbonate system, as can occur during intense photosynthetic CO₂ fixation of large phytoplankton cells (Wolf-Gladrow and Riebesell 1997). For small algal cells, the expected disequilibrium due to photosynthetic CO₂ fixation is too small for eCA to significantly enhance CO₂ availability at the cell surface. For instance, assuming a 25-fold enhancement in the conversion of HCO⁻ to CO₂ (as determined by Elzenga et al. 2000) in the diffusive boundary layer of a 5-μm diameter algal cell growing at a rate of 1 d⁻¹, Riebesell and Wolf-Gladrow (2002) calculated an increase in the cell surface CO₂ concentration due to CA-catalyzed HCO⁻ conversion of only 0.04 μmol L⁻¹. Although this number increases to 0.25 μmol L⁻¹ for a cell of 10-μm diameter, it is still small compared to the ambient CO₂ concentrations of ~10 μmol L⁻¹. In view of these considerations it is puzzling, however, that the addition of CA to a culture of *E. huxleyi* (with a cell diameter of ca. 6 μm) resulted in a nearly 30% stimulation of photosynthesis in 2 mmol L⁻¹ dissolved inorganic carbon and a pH of 8.1 (Sikes and Wheeler 1982). One possible explanation for the widespread occurrence of eCA in microalgae could be a direct involvement of this enzyme in an uptake system for CO₂ or HCO₃⁻ as suggested for cyanobacteria by Kaplan and Reinhold (1999).

The physiological role of intracellular CA, which can be
C acquisition of marine phytoplankton

Fig. 6. *P. globosa*. Chl *a*–specific rates of net photosynthesis, gross CO₂ uptake, and HCO₃⁻ uptake as a function of CO₂ and HCO₃⁻ concentration in the assay medium. The cultures were acclimated to (a), (b) 1,800 ppmv, (c), (d) 360 ppmv, (e), (f) 180 ppmv, or (g), (h) 36 ppmv of CO₂ for at least 3 d. Curves were obtained from a Michaelis–Menten fit.

located in the chloroplast and the mitochondria, as well as the cytosol, remains unclear (Sültemeyer 1998). When interpreting iCA activities according to Palmqvist et al. (1994), one has to bear in mind that Δ values are dependent on the rate of diffusive CO₂ transport across cell membranes and the rate of extracellular and intracellular ¹⁸O depletion. Figure 1 shows an example for the log (enrichment) of *P. globosa* acclimated to 36 ppmv CO₂. Since the same amount of cells were injected, the curves are directly comparable. As shown in this example, significantly different Δ values were obtained in the presence and absence of the eCA inhibitor DBS. In contrast with the results of Palmqvist et al. (1994), we therefore conclude that the eCA activity alters the estimates of and may even impose a trend on iCA activity. Although we used DBS in all iCA assays, Δ values remain arbitrary units, which allows direct comparison of different treatments but not between species. Results of Burkhardt et al. (2001) indicate a gradual increase in iCA activity of two marine diatoms in response to diminishing CO₂ supply. Our data do not confirm such a CO₂ dependence in iCA activity in the species tested since iCA activities increased at very low pCO₂ levels only for *S. costatum*. This may indicate that the response of iCA activity to reduced CO₂ levels is species dependent.

Light-stimulated ¹⁸O exchange—Using the ¹⁸O exchange technique, we examined the presence of light-dependent Ci transport systems. A potential influence by light activation of eCA (Nimer et al. 1998) was excluded by the presence of DBS during the assay. In the case of active Ci uptake, a large decline in log (enrichment) during illumination would be expected, which is caused by an enhanced influx of ¹⁸O-labeled CO₂ and HCO₃⁻ into the cells to the active site of intracellular CA, increased ¹⁸O loss, and subsequent efflux of ¹⁸O unlabeled CO₂ (Badger and Price 1989; Palmqvist et al. 1994). Such a net CO₂ efflux from photosynthetically active cells due to leakage through the cell membrane can be explained by accumulation of CO₂ inside the cell relative to ambient CO₂ concentration. As shown in Fig. 4, illumination of 1,800 ppmv CO₂ grown cells of *S. costatum* and
Fig. 7. *E. huxleyi*. Chl-a-specific rates of net photosynthesis, gross CO₂ uptake, and HCO₃⁻ uptake as a function of CO₂ and HCO₃⁻ concentration in the assay medium. The cultures were acclimated to (a), (b) 1,800 ppmv, (c), (d) 360 ppmv, (e), (f) 180 ppmv, or (g), (h) 36 ppmv of CO₂ for at least 3 d. Curves were obtained from a Michaelis–Menten fit.

*P. globosa* resulted in a rapid uptake of ¹³C¹⁸O₂ (m/z = 49) and a large efflux of ¹³CO₂ (m/z = 45), i.e., a light-dependent decrease in log (enrichment). The involvement of a rapid induction of eCA activity (Nimer et al. 1998) in this process can be ruled out since we added DBS to the reaction assay in order to inhibit eCA. A likely explanation of the observed changes in ¹⁸O exchange therefore is the presence of CCM associated Ci uptake systems even in cells grown under elevated CO₂ concentrations. The apparently greater lag phase for *S. costatum* could be explained by a lower leakage or slower induction of the Ci uptake in this species. In *E. huxleyi* the light-stimulated ¹⁸O exchange is not present in 1,800 ppmv CO₂ grown cells (not shown) and far less pronounced in cells acclimated to 360 ppmv CO₂ (Fig. 4), which indicates that Ci transport in this species is only induced at lower CO₂ levels.

**Photosynthetic O₂ evolution**—Monitoring photosynthetic O₂ evolution as a function of CO₂ concentration provides important information about the carbon acquisition of microalgae. CO₂-induced changes and generally lower $K_{1/2}$(CO₂) values than $K_M$(CO₂)RubisCO indicate the operation of a CCM. *S. costatum* strongly regulates its CCM, which is shown by the large changes in $K_{1/2}$ for photosynthesis (Fig. 5; Table 2). According to our results *P. globosa* has a highly efficient CCM but apparently does not regulate in response to CO₂ supply as indicated by more or less constant values of $K_{1/2}$ for O₂ evolution over a wide range of pCO₂ (Fig. 6, Table 2). The high values of $K_{1/2}$ for *E. huxleyi* (Fig. 7, Table 2) imply that photosynthesis in this species is not even carbon saturated under conditions commonly found in the ocean. Nevertheless, *E. huxleyi* showed some degree of regulation in its carbon acquisition, which is shown by the CO₂-induced changes in the $K_{1/2}$. The operation of a CCM in this strain of *E. huxleyi* was previously predicted from $δ^{13}$C isotope fractionation experiments by Rost et al. (2002). Another highly calcifying strain of *E. huxleyi* was shown to induce a CCM toward the stationary phase (Nimer and Merrett 1996).

The efficiency of a CCM may be assessed from the ratio...
Carbon uptake kinetics—Various methods have been employed to distinguish between \( K_m \) (\( \text{CO}_2 \)) of RubisCO and the apparent \( K_{1/2} \) (\( \text{CO}_2 \)) of \( \text{O}_2 \) evolution. This ratio approximates the enrichment in internal \([\text{CO}_3]\) at the site of RubisCO compared to the ambient \([\text{CO}_2]\). For our calculations we used previously reported \( K_m \) values for RubisCO (Badger et al. 1998) and \( K_{1/2} \) values obtained in this study (Table 2). While the \( K_{1/2} \) \( K_{1/2} \) ratio increased with decreasing \( \text{CO}_2 \) concentrations in incubations of \( S. \text{costatum} \) and \( E. \text{huxleyi} \), it showed no trend for \( P. \text{globosa} \) (Fig. 8a), again indicating that the latter species does not regulate its CCM in relation to external \( \text{CO}_2 \) concentrations. \( S. \text{costatum} \) reached the highest values of up to 120, whereas \( K_{1/2} \) \( K_{1/2} \) ratios of \( E. \text{huxleyi} \) ranged between 1 and 3. These results are consistent with the observed species-specific patterns of light-stimulated \( \text{O}_2 \) exchange. Although the \( \text{CO}_2 \) dependence in \( \text{O}_2 \) evolution reveals information about the efficiency and regulation of the CCM, it cannot provide any details about the underlying mechanisms.

Carbon uptake kinetics—Various methods have been employed to distinguish between \( \text{CO}_2 \) and \( \text{HCO}_3^- \) uptake in microalgae. In this study estimates of \( \text{CO}_2 \) and \( \text{HCO}_3^- \) uptake rates were obtained by a method of Badger et al. (1994), which has the advantage that inorganic carbon fluxes can be quantified at steady-state photosynthesis. While this method has successfully been applied to cyanobacteria and several freshwater microalgae (Badger et al. 1994; Tchernev et al. 1997; Amoroso et al. 1998), it has only recently been used to examine two marine diatoms (Burkhardt et al. 2001). Our observation of simultaneous \( \text{CO}_2 \) and \( \text{HCO}_3^- \) uptake for marine phytoplankton is consistent with the results of previous studies (e.g., Colman and Rotatore 1995; Burkhardt et al. 2001). The uptake kinetics for both substrates differ strongly between the investigated species (Table 2).

In \( S. \text{costatum} \) the \( \text{CO}_2 \) and \( \text{HCO}_3^- \) uptake systems showed high affinities even at 1,800 ppmv \( \text{CO}_2 \), which increased even more with decreasing \( \text{pCO}_2 \) in the incubation (Fig. 5). Concomittantly, the contribution of \( \text{HCO}_3^- \) to the overall carbon acquisition increased. A possible explanation for the increase in substrate affinity could either be posttranslational regulation (Sülttemeyer et al. 1998) or an increasing expression of a high affinity uptake system, as has already been suggested for cyanobacteria (Shibata et al. 2002). The larger contribution of \( \text{HCO}_3^- \) is the result of an increasing number of transport components with decreasing \( \text{CO}_2 \) concentrations. Direct uptake of \( \text{HCO}_3^- \) has previously been suggested for \( S. \text{costatum} \) (Korb et al. 1997) but has hitherto not been quantified.

In \( P. \text{globosa} \), the affinities of the \( \text{CO}_2 \) and \( \text{HCO}_3^- \) uptake system were high and showed no trend with \( \text{pCO}_2 \) in the incubation (Fig. 6), which is consistent with our results for \( \text{O}_2 \) evolution. Elzenga et al. (2000) concluded from their results that \( P. \text{globosa} \) uses \( \text{HCO}_3^- \) by means of CA-mediated conversion to \( \text{CO}_2 \), which then diffuses across the membrane. The high activities of eCA and the inhibition of \( \text{O}_2 \) uptake of \( \text{HCO}_3^- \) uses \( \text{CO}_2 \) as the substrate of conversion to \( \text{CO}_2 \), which then diffuses across the membrane. One has to consider, however, that a prerequisite of the carbon flux measurement of eCA activity. In the presence of eCA activity the proportion of direct \( \text{HCO}_3^- \) uptake to the overall carbon acquisition might be smaller because of an increasing indirect use of \( \text{HCO}_3^- \). In contrast to the results of Elzenga et al. (2000), we did not find a gradual induction in \( \text{HCO}_3^- \) use. Yet it seems that direct \( \text{HCO}_3^- \) uptake and eCA-mediated \( \text{HCO}_3^- \) use are more pronounced in the lowest \( \text{pCO}_2 \) incubation.

The high \( K_{1/2} \) values for \( \text{O}_2 \) evolution of \( E. \text{huxleyi} \) are
reflected in the relatively low affinities of the CO$_2$ uptake system. The uptake of HCO$_3^-$ could not be described by Michaelis–Menten kinetics, which is consistent with findings of Nimer and Merrett (1992). While the CO$_2$ uptake system largely reflects the kinetics of the O$_2$ evolution, the HCO$_3^-$ uptake seems to provide a constant background flux of inorganic carbon. The latter may point to an involvement of the calcification process in HCO$_3^-$ use of *E. huxleyi*. It has previously been suggested that calcifying strains of *E. huxleyi* are able to produce CO$_2$ by the process of calcification, which is then used for photosynthetic C fixation (e.g., Sikes et al. 1980; Nimer and Merrett 1992). Coccolith formation in *E. huxleyi* could thereby serve to partly compensate for the low efficiency of its CCM. The extent to which photosynthesis and calcification are linked and whether calcification supports photosynthetic carbon acquisition is still under debate.

To mimic natural seawater carbonate chemistry we did not add any artificial buffer to the culture media. As pointed out by Burkhart et al. (2001), buffers have a pronounced effect on the carbonate system as they keep the ratio of [HCO$_3^-$]:[CO$_2$] constant despite changes in pCO$_2$. In natural seawater, changes in CO$_2$ concentration are accompanied by respective changes in pH and the [HCO$_3^-$]:[CO$_2$] ratio. In our experiments, changes in pCO$_2$ from 36 to 1,800 ppmv resulted in a decrease in pH from 9.1 to 7.6 and a decrease in [HCO$_3^-$]: [CO$_2$] ratio from 767 to 32, respectively. Using uptake kinetics obtained in this study and the corresponding carbonate system speciation for each of the pCO$_2$ incubations we calculated the ratio of gross CO$_2$ to HCO$_3^-$ uptake (Fig. 8b). Values larger than 1 indicate a preference for CO$_2$, values below 1 a preference for HCO$_3^-$ as carbon source. While the three species take up both CO$_2$ and HCO$_3^-$ over the entire range of CO$_2$ concentrations tested, CO$_2$ was the preferred substrate in all but the lowest CO$_2$ incubation. Under air-equilibrated CO$_2$ concentrations, the cells take up about twice as much CO$_2$ as HCO$_3^-$.

A gradual induction of HCO$_3^-$ uptake occurred with decreasing pCO$_2$ in the incubation, with *S. costatum* showing the largest and *P. globosa* the smallest changes between treatments.

The calculation of these uptake ratios is based on the assumption that the CO$_2$ and HCO$_3^-$ uptake systems are regulated independently of each other and that changes in pH have no significant effect on uptake kinetics. Unlike the conditions in our pCO$_2$ controlled incubations, the [HCO$_3^-$]:[CO$_2$] ratio in the assays remained constant. If this ratio has an effect on the regulation of the different uptake systems, the calculations would lead to erroneous estimates of uptake kinetics in the culture. Microalgae with a preference for CO$_2$, for instance, might cover a larger proportion of their total inorganic carbon uptake by CO$_2$ at the low [HCO$_3^-$]:[CO$_2$] ratio of a high pCO$_2$ culture (pH 7.6) than under the higher [HCO$_3^-$]:[CO$_2$] ratio in the assay (pH 8.0). Another critical point is that the gross CO$_2$ uptake might be underestimated as a result of cell compartmentation (Badger et al. 1994). An increased CA-mediated HCO$_3^-$ use, which is inhibited in the assay by DBS, could decrease the direct uptake of HCO$_3^-$. All of these factors would lead to an increase in the CO$_2$ : HCO$_3^-$ uptake rates compared to our calculated values. In other words, the calculation could underestimate the contribution of CO$_2$. The presence of HCO$_3^-$ leakage, as suggested by Tchernov et al. (1997), however, would increase HCO$_3^-$ uptake rates and thus decrease the CO$_2$ : HCO$_3^-$ uptake ratio. For an in-depth assessment of these methodological uncertainties we refer to Badger et al. (1994), Kaplan and Reinhold (1999), and Burkhart et al. (2001).

**Ecological and biogeochemical implications**—Although most phytoplankton species reach photosynthetic saturation under ambient CO$_2$ levels (Raven and Johnston 1991), this does not imply that species are equally efficient in their carbon acquisition. In fact, phytoplankton species differ significantly in the extent to which they actively transport HCO$_3^-$ and/or CO$_2$ and accumulate inorganic C intracellularly (Raven 1997; Badger et al. 1998). As pointed out by Tortell (2000), the efficiency of the CCM of different taxonomic groups seems to be negatively correlated with the catalytic efficiency of their RubisCO. Our results indicate large differences in both efficiency and regulation of inorganic carbon acquisition for representatives of three phytoplankton functional groups. These differences may affect the relative fitness of the different groups and thus could help to explain the distribution and succession of phytoplankton in space and time.

Microalgae with regulated CCMs can optimize the allo-
cation of resources for operating carbon acquisition mechanisms in response to changing growth conditions. Part of this regulation is the observed preference for CO$_2$ under elevated CO$_2$ concentrations, since CO$_2$ uptake is considered to be less costly than HCO$_3^-$ uptake (Raven 1990). Under severe CO$_2$ limitation, however, HCO$_3^-$ uptake becomes increasingly important despite presumably higher costs. Consistent with the cost–benefit strategy is also the up-regulation of the eCA activities as CO$_2$ concentrations decrease. CCM activity is also influenced by the energy (light) supply. For example, light limitation was found to decrease the capacity of Ci transport (Shiraiwa and Miyachi 1983; Beardall 1991). Based on carbon isotope fractionation experiments, Rost et al. (2002) proposed that both photon flux density and day-length influence the regulation of active carbon uptake in E. huxleyi, presumably by modulating the Ci demand of the cell. In fact, the duration of the photoperiod was shown to influence the operation of the CCM in the three species tested in this study (Rost et al. unpubl.).

Despite the ability of most phytoplankton species to regulate their carbon acquisition, large differences exist in the efficiencies. Owing to their highly efficient CCMs, photosynthetic carbon fixation rates of all diatom species tested so far, as well as of P. globosa, are at or close to CO$_2$ saturation at present day CO$_2$ levels (e.g., Raven and Johnston 1991; Burkhardt et al. 2001; this study). In contrast, coccolithophorids such as E. huxleyi seem to be well below saturation at these levels (Paasche 1964; Nielsen 1995; Riebesell et al. 2000; this study) and thus are more CO$_2$ sensitive. In fact, although the cell division rate of E. huxleyi remains more or less constant over a wide range of CO$_2$ concentrations, carbon fixation rate and carbon-specific growth rate are strongly CO$_2$ dependent (Raven 1990; Rost et al. 2002), reflecting the low efficiency of its CCM.

According to the ecological aspects discussed above, differences in inorganic carbon acquisition may play a role for the competitive advantage of marine phytoplankton. Bloom-forming species should be especially dependent on a regulated and efficient CCM, since they must maintain high growth rates even under conditions in a bloom, when CO$_2$ concentrations decrease due to photosynthetic carbon consumption (down to $\sim$5 $\mu$mol L$^{-1}$). By the end of this century, the expected increase in the atmospheric CO$_2$ will give rise to an almost threefold increase in surface water CO$_2$ concentrations relative to preindustrial values. This will cause the [HCO$_3^-$]:[CO$_2$] ratio and seawater pH to decrease by ca. 65% and 0.35 units, respectively (Wolf-Gladrow et al. 1999). These changes are likely to affect phytoplankton, yet in different ways. Microalgae that react to ambient CO$_2$ concentrations, as shown for S. costatum and E. huxleyi, may have advantages in the future compared to preindustrial or glacial times owing to the potential reduction in their CCMs. Phytoplankton productivity based on carbon or energy content might therefore increase under typically resource-limiting conditions in the ocean (Raven and Johnston 1991). CO$_2$-sensitive coccolithophorids such as E. huxleyi may benefit even more from the present increase in atmospheric CO$_2$ when compared to diatoms and Phaeocystis. Since coccolithophorid blooms predominantly occur in well-stratified waters that are expected to extend and intensify in the future (Sarmiento et al. 1998), projected climate-induced changes in the marine environment may prove even more advantageous for this group of phytoplankton.

According to the functional group concept (Falkowski et al. 1998) diatoms, Phaeocystis, and coccolithophorids each play a specific role in the marine ecosystem and have distinct effects on elemental cycling. One of the most prominent examples is the differential impact of calcifying and noncalcifying phytoplankton on the CO$_2$ air–sea exchange. While the latter drive the organic carbon pump, which releases CO$_2$ into the environment (Robertson et al. 1994). As discussed above, rising CO$_2$ levels and increasing stratification might increase the contribution of the calcifying phytoplankton to overall primary production, which consequently would increase the ratio of calcification to organic carbon production. An increase in this ratio, which might result from an increased contribution of coccolithophorids, would enhance the relative strength of the carbonate pump. This in turn would lower the biologically mediated CO$_2$ uptake from the atmosphere. A basin-wide shift in the composition of sediment particles, as indicated by a decrease of the opal:carbonate ratio, has in fact been observed across the entire North Atlantic and is suggested to be related to large-scale changes in climate forcing (Antia et al. 2001). These findings are consistent with high concentrations of coccoliths observed in interglacial sediments, whereas glacial sediments are poor in biogenic carbonate (e.g., Henrich 1989).

On the other hand, there are indications that rising atmospheric CO$_2$ may affect marine biogenic calcification in yet another way. Rates of calcification of dominant calcifying organisms such as corals, foraminifera, and coccolithophorids were shown to decrease under elevated CO$_2$ concentrations (Kleypas et al. 1999; Bijma et al. 1999; Riebesell et al. 2000). A CO$_2$-related reduction in calcification decreases the ratio of calcification to organic matter production. With ca. 80% of the global CaCO$_3$ production contributed by planktonic organisms, reduced calcification decreases the strength of the calcium carbonate pump and thereby increases the biologically driven draw down of CO$_2$ by the surface ocean (Zondervan et al. 2001). The climate-induced increase in the contribution of coccolithophorids to total primary production and a CO$_2$-related decrease in biogenic calcification would have opposing effects on the marine carbon cycle. Their net effect on carbon cycling will depend on their relative importance and sensitivity to global change. Changes in marine production, phytoplankton species composition, and succession will also impact other biogeochemical cycles, such as nitrogen, opal, and sulfur cycles, which in turn is bound to feed back on the climate.

In conclusion, the results of this study revealed species-specific differences in CO$_2$-dependent photosynthetic O$_2$ evolution, substrate affinities, relative contribution of HCO$_3^-$ to total carbon uptake and eCA activity as well as differences in the degree of pCO$_2$-dependent regulation. Our results indicate a highly efficient and regulated carbon acquisition for S. costatum, which can be ascribed to increasing affinities in the CO$_2$ and HCO$_3^-$ uptake systems, an increasing contribution of HCO$_3^-$ to the overall carbon acquisition,
and an increase in eCA activity with decreasing pCO₂. *P. globosa* showed a highly efficient but rather constitutive carbon acquisition, which was reflected in the high affinities of the CO₃ and HCO₃ uptake systems, a constant contribution of HCO₃ to the overall carbon acquisition, and high eCA activities independent of the pCO₂. For *E. huxleyi* an inefficient albeit regulated carbon acquisition was observed, with low affinities in the inorganic carbon uptake systems and low eCA activities. If observed differences between these species are representative for the corresponding phytoplankton functional groups in the natural environment, CO₂-related changes in seawater chemistry are expected to modify phytoplankton species succession and distribution. Responses in phytoplankton communities, especially shifts in the dominance between functional groups, are likely to influence biogeochemical cycling. Effects of elevated CO₂ on the physiology and ecology of phytoplankton have to be assessed in more detail, especially with respect to their feedback on ecosystem regulation and global biogeochemical cycles.
