Accepted 13 December 1989

Summary

The intracellular pH (pHi) of the anterior byssus retractor muscle (ABRM) of Mytilus edulis L. was estimated during rest and during a contraction–catch–relaxation cycle by the distribution of $^{14}$C]DMO and by $^{31}$P-NMR spectroscopy. The pHi of resting muscles was found to be nearly the same whether it was determined with DMO (7.41±0.06, N=5) or by $^{31}$P-NMR spectroscopy (7.44±0.02, N=5). During catch the pHi was not significantly different from its value at rest. Serotonin ($10^{-5}$ mol$^{-1}$) induced a rapid relaxation and a significant increase in pHi (DMO: 7.56±0.05, N=11; $^{31}$P-NMR: 7.57±0.02, N=5). In resting ABRM serotonin (≥$10^{-6}$ mol$^{-1}$) also induced an alkalinosis. It was shown that cyclic AMP, the second messenger of serotonin, elicited an increase of pHi. Dopamine ($10^{-5}$ mol$^{-1}$) did not cause an increase in either cyclic AMP levels or pHi. The rates by which tonically contracted ABRM loaded at 0.1 N were stretched were significantly increased by an alkalinosis elicited by the addition of 10 or 20 mmol$^{-1}$ methylamine. Acidosis elicited by 10 mmol$^{-1}$ DMO caused a significant decrease in the rate of relaxation.

Introduction

The anterior byssus retractor muscle (ABRM) of the common sea mussel Mytilus edulis L. is able to perform two different types of contraction distinguished by their velocity of relaxation. Phasic contraction is characterized by rapid relaxation, whereas tonically contracted muscles relax very slowly. The active phase of a contraction is elicited by acetylcholine. During a tonic contraction the active phase is followed by a passive phase called catch (for reviews, see Rüegg, 1971; Twarog, 1979). During catch the ABRM is able to maintain tension or

Key words: ABRM, catch, intracellular pH, serotonin, cyclic AMP.
shortening for long periods, although the metabolic rate is reduced almost to resting levels (Baguet and Gillis, 1968; Zange et al. 1989).

The molecular mechanism of catch is still unknown. Two main hypotheses are presently discussed. The cross-bridge hypothesis proposes that cross-bridge cycling is reduced to the resting value, but the phase of cross-bridge attachment is prolonged owing to an increased affinity of myosin for actin (Lowy et al. 1964; Takahashi et al. 1988). The paramyosin hypothesis proposes a cross-linking of the thick filaments, presumably through paramyosin (Rüegg, 1971; Hauck and Achazi, 1987).

Serotonin (Twarog, 1954), dopamine (Twarog and Cole, 1972) and electrical stimulation by alternating current pulses (Winton, 1937; Fletcher, 1937) abolish catch and lead to a rapid relaxation. Achazi et al. (1974) found that serotonin stimulates an adenylate cyclase system. They proposed that the increased levels of cyclic AMP finally lead to a phosphorylation or dephosphorylation of the paramyosin involved in catch performance. This mechanism of catch relaxation has been questioned, because serotonin affects catch at concentrations as low as $10^{-9}$ mol$^{-1}$ (Twarog, 1954), but $10^{-6}$ mol$^{-1}$ serotonin is needed to increase the content of cyclic AMP significantly (Köhler and Lindl, 1980). Furthermore, dopamine has little or no effect on cyclic AMP levels (Köhler and Lindl, 1980; Ishikawa et al. 1981).

Experiments with skinned fibres from ABRM$s$ indicated that intracellular pH (pHi) may be involved in catch regulation. This preparation is able to enter a catch-like state when Ca$^{2+}$ has been removed after an active contraction. The catch-like state of skinned fibres is sensitive to changes in the pH of the incubation medium. Between pH values of 6.2 and 6.7 skinned fibres relax slowly, whereas pH values higher than 7.0 cause a fast drop of the maintained tension or shortening (Johnson, 1959; Rüegg, 1971; Pfitzer and Rüegg, 1982). Another argument for an involvement of pHi in catch regulation is the observation that living ABRM$s$ reduce their relaxation velocity during catch when they are acidified by incubation in a medium containing high concentrations of CO$_2$ (Rüegg, 1964).

The present study was designed to estimate the pHi of the ABRM during rest and during a contraction–catch–relaxation cycle. pHi was measured either by the distribution of $[^{14}C]$dimethylxazolidine-2,4-dione (DMO; Waddell and Butler, 1959) or by $^{31}$P-NMR spectroscopy (Moon and Richards, 1973). Further DMO studies focused on the relationship between cyclic AMP levels and pHi. Lastly, the effect of changes in pHi, elicited by the application of either a weak base or a weak acid, on relaxation velocity of the ABRM during catch was investigated.

Materials and methods

Animals

Mussels Mytilus edulis L. were obtained from the Nederlands Instituut voor Onderzoek der Zee, Den Helder, The Netherlands. The animals were kept in
pHi of a catch muscle during tonic contraction

recirculating, filtered artificial sea water (32 %) for 3–12 weeks at 15±1°C until they were used in the experiments.

Preparation and incubation

When pHi was estimated using the DMO method, the isolation of the ABRM followed the procedure of Hoyle and Lowy (1956). Intact muscles were attached to a piece of shell and held by a silk thread tied to the byssal end of a muscle. The mussel contains a pair of identically shaped ABRMs. For each experiment both muscles were taken. For contraction experiments, one muscle of a pair was taken as a resting control and the other was used in the experiment.

The muscles were mounted in incubation chambers filled with a seawater medium equilibrated with air at 15±1°C and pH 7.65. Resting and contracting muscles were loaded with a weight of 0.1 N. Since freshly prepared ABRMs were usually contracted, isolated muscles were subjected to electrical stimulation with rectangular pulses applied by platinum electrodes (2 Hz, 100 ms, 10 V; Winton, 1937). Muscles were then incubated for 4 h before the experiment was started.

When pHi was monitored using 31P-NMR spectroscopy silk threads were tied to both ends of the muscles prior to separation of the ABRMs from the byssus and the shell. For each series of experiments four or five ABRMs with a total wet mass of 100–150 mg were used. The muscles were tied at their shell ends to a muscle holder placed at the bottom of a 10 mm NMR tube. Using the threads tied to the byssal ends of the muscles, the ABRMs were arranged vertically within the NMR tube. The tube was filled with 4 ml of air-equilibrated seawater medium at 15±1°C and a pH of 7.65±0.02. A gas-inlet capillary was placed 0.5 cm above the sensitive range of the receiver coil.

Recording of muscle movements

Changes in muscle length were followed by means of an isotonic transducer connected to an HF modem and an amplifier (Hugo Sachs Electronic, Freiburg, FRG) and were displayed on a chart recorder.

Tonic contractions

In cases where DMO was used to estimate pHi, tonic contractions under isotonic conditions (0.1 N) were elicited by the application of acetylcholine (0.5 mmol l⁻¹; Nauss and Davies, 1966) to a single muscle. The ABRM contracted maximally within 1 min. Two minutes after the addition of acetylcholine, the transmitter substance was washed out using two washes of acetylcholine-free medium. The second medium contained [³¹⁴C]DMO and [³¹H]inulin.

During NMR experiments, the pHi of four simultaneously contracting ABRMs was monitored. The transducer was placed 5 m away from the spectrometer to avoid damage by the magnetic field. The average isotonic shortenings of these four muscles, which were each loaded with 0.1 N, were transmitted to the transducer using an arrangement of three plastic rings working like a tackle block. Contraction was again elicited by the application of acetylcholine (0.5 mmol l⁻¹).
Acetylcholine was washed out after 3 min by the use of a glass capillary placed on the muscle holder.

**Determination of pH by the distribution of DMO**

Intracellular pH was determined by application of the DMO distribution method (Waddell and Butler, 1959) to an ABRM incubated in a medium containing [\(^{14}\)C]DMO (1.5 \times 10^5 disits min\(^{-1}\) ml\(^{-1}\), <2 nmol l\(^{-1}\)) and [\(^{3}\)H]insulin (2 \times 10^5 disits min\(^{-1}\) ml\(^{-1}\)). Both labelled substances were obtained from Amersham Buchler, Braunschweig, FRG. Details of the analysis of \(^{14}\)C and \(^{3}\)H activity in the muscle and in the medium, of the measurement of medium pH and of the calculation of pH have been described previously (Pörtner et al. 1984).

**NMR spectroscopy**

All \(^{31}\)P-NMR spectra were recorded at 161.5 MHz on a Bruker AM400WB spectrometer. Typical acquisition parameters were: sweep width 10000 Hz, pulse width 7.4 \(\mu\)s (corresponding to a 45° flip angle), 4096 data points, relaxation delay 0.132 s and acquisition time 0.205 s. For each spectrum, 512 scans were accumulated within 2.94 min.

**Determination of the intracellular pH by \(^{31}\)P-NMR**

pHi was determined from the chemical shift of the intracellular inorganic phosphate relative to the shift of glycerophosphorylcholine (GPC) as an extracellular chemical shift standard. The chemical shift of GPC (+0.49 p.p.m.) is unaffected by changes in pH. To relate the chemical shift to pH a muscle extract was titrated. This titration curve (see Zange et al. 1990) was used to obtain the relationship between the chemical shift of inorganic phosphate and pHi.

**Analysis of cyclic AMP levels**

ABRMs were ground in a small mortar under liquid nitrogen as described by Pette and Reichmann (1982). The concentrations of cyclic AMP were measured in neutralized trichloroacetic acid extracts using a radioimmunoassay test kit obtained from Amersham Buchler, Braunschweig, FRG.

**Medium**

The seawater medium used for the DMO experiments had the following composition (in mmol l\(^{-1}\)): NaCl, 463; KCl, 10; MgCl\(_2\), 24; MgSO\(_4\), 28; CaCl\(_2\), 10 and Heps/NaOH, 5 (pH 7.65). HCO\(_3\)\(^-\) (0.4 mmol l\(^{-1}\)) was formed during equilibration with air (\(P_{CO_2} = 0.03\) kPa). For NMR experiments the concentrations of NaCl and of Heps were changed to 438 and 30 mmol l\(^{-1}\), respectively.

**Statistical analysis of the results**

The significance of a difference between two values of pHi (mean\(\pm\)s.d.) was tested using Student’s t-test (\(P<0.05\)).
Results

\textit{pHi during a contraction–catch–relaxation cycle}

\textit{The estimation of pHi with DMO}

In relaxed, maximally stretched ABRMs loaded with 0.1 N, equilibration with DMO and inulin was reached within 15 min. Maximally contracted, unloaded muscles were equilibrated within 45 min, whereas the time for equilibration in tonically contracted ABRMs, which were slowly stretched by a load of 0.1 N during catch, was 30 min.

In resting ABRMs a pHi of 7.41±0.06 (N=51) was estimated by the distribution of DMO. In ABRMs in catch (30 min) pHi did not change significantly (7.42±0.05, N=10). In muscles in catch for 15 min and then rapidly relaxed by application of serotonin (10^{-5}\text{ mol}\text{l}^{-1}) for a further 15 min, pHi was significantly increased to 7.56±0.05 (N=11; see Fig. 1 and Table 1). Owing to the slow distribution of DMO, pHi measurements could not be performed using this method during the active contraction. Therefore, the \textsuperscript{31}P-NMR technique was employed.

\textit{pHi determined by \textsuperscript{31}P-NMR spectroscopy}

pHi was monitored continuously in intervals of 3 min (512 scans) during rest and during a contraction–catch–relaxation cycle. In resting muscles a pHi of

Values are mean±s.d. pH\textsubscript{i} was estimated with DMO.

7.44±0.02 (N=5) was estimated. During the active phase of contraction lasting for 3 min, pH\textsubscript{i} increased significantly to 7.54±0.01 (N=5). During the subsequent catch pH\textsubscript{i} dropped back to resting levels within 3 min. Serotonin (10\textsuperscript{-5} mol\textsuperscript{-1}L\textsuperscript{-1}) elicited a rapid relaxation and a slow increase of pH\textsubscript{i}. About 1 min after application of serotonin, the ABRMs were stretched at a maximal rate. At this time, pH\textsubscript{i} had still not increased significantly (7.45±0.03). pH\textsubscript{i} reached its maximum of 7.57±0.02 after 15–20 min. At this time the muscles had relaxed (see Fig. 2).

The effect of serotonin on resting ABRMs

Application of serotonin (10\textsuperscript{-5} mol\textsuperscript{-1}L\textsuperscript{-1}) to resting muscles for 15 min also elicited a significant alkalization (pH\textsubscript{i} 7.52±0.04, N=12, DMO method). pH\textsubscript{i} remained elevated (7.58±0.03, N=12, DMO method, see Table 1) for 4.5 h.

The effect of serotonin on pH\textsubscript{i} in ABRMs was dose-dependent. Concentrations of 10\textsuperscript{-7} mol\textsuperscript{-1}L\textsuperscript{-1} or lower did not change pH\textsubscript{i} significantly (7.45±0.01, N=3, NMR method), but serotonin applied at concentrations of 10\textsuperscript{-6} mol\textsuperscript{-1}L\textsuperscript{-1} or greater increased pH\textsubscript{i} maximally (7.59±0.02; see Fig. 3).

The relationship between cyclic AMP levels and pH\textsubscript{i}

In resting control muscles, cyclic AMP levels were estimated to be 3.2±0.2 nmol g\textsuperscript{-1} wet mass (N=6). Serotonin (10\textsuperscript{-5} mol\textsuperscript{-1}L\textsuperscript{-1}, 15 min) induced a significant increase in cyclic AMP levels to 38.9±8.4 nmol g\textsuperscript{-1} (N=6). Therefore, we were interested in the question of whether cyclic AMP, as the second messenger of serotonin, causes an increase in pH\textsubscript{i}.

To simulate the effect of serotonin on cyclic AMP levels we used forskolin, which is known to stimulate adenylate cyclase (Seamon and Daly, 1981) and IBMX (isobutyl-1-methylxanthine), an inhibitor of phosphodiesterase (Pannabecker and Orchard, 1986). A significant increase in cyclic AMP levels (8.4±1.5 nmol g\textsuperscript{-1}) could be induced only if forskolin (50 μmol L\textsuperscript{-1}) and IBMX (1 mmol L\textsuperscript{-1}) were applied together.

In resting ABRMs, forskolin and IBMX induced a significant alkalization
pHi of a catch muscle during tonic contraction

(7.59±0.03, N=12, DMO method; Table 2). The application of 8-bromo-cyclic AMP (8-Br-cAMP) (5 mmol L⁻¹) to isotonically contracted ABRMs during catch also elicited a significant increase in pHi (7.53±0.05, N=9, DMO method; Table

2). Therefore, it seems likely that serotonin induces an increase in pH i via cyclic AMP as a second messenger.

In those experiments in which the effect of serotonin (10⁻⁵ mol l⁻¹) on catch and pH i was investigated, the isotonically contracted ABRMs loaded with 0.1 N were extended at a rate of 0.05±0.02 mm min⁻¹ (N=9) during catch. Serotonin induced a maximum relaxation rate of 5.0±1.8 mm min⁻¹ after 1 min.

Before 8-bromo-cyclic AMP was added to the isotonically contracted ABRMs, the muscles stretched at a rate of 0.05±0.02 mm min⁻¹ (N=9). This rate was significantly increased to 0.18±0.08 mm min⁻¹ within 15 min of 8-bromo-cyclic AMP application. The maximal rate of relaxation induced by serotonin was 28 times faster than that induced by 8-bromo-cyclic AMP.

The catch-releasing transmitter dopamine (10⁻⁵ mol l⁻¹) did not elicit significant changes in pH i (7.45±0.03, N=12, DMO method) or in cyclic AMP levels (3.4±0.5 nmol g⁻¹, N=6; Table 2).

The relationship between pH i and the rate of relaxation during catch

The rate at which an ABRM was stretched by a load of 0.1 N (Vₘ, mm min⁻¹) was used as an indicator of the holding capacity of the muscle during catch. Vₘ was not significantly correlated with the wet mass or with the muscle tension (N cm⁻²). Therefore, experiments were conducted without any standardization of Vₘ.

Our results show that alkalization elicited by the weak base methylamine (10 or 20 mmol l⁻¹) induced a significant acceleration of Vₘ, whereas acidification elicited by unlabelled DMO (10 mmol l⁻¹) induced a significant decrease in Vₘ (Table 3).

$V_s$ was measured before ($V_{s1}$) and after ($V_{s2}$) treatment. pH i was estimated using [$^{13}$C]DMO. ΔpH i was calculated relative to the pH i of resting control muscles (7.41, see Table 1). Values are mean±s.d.

(pHi = 7.54±0.05, N=8, DMO method) on $V_s$ (0.16±0.04 mm min$^{-1}$) was similar to the effect of 8-bromo-cyclic AMP on pH i and $V_s$.

Discussion

The pH i of resting ABRMs was found to be 7.41±0.06 (N=51, DMO method) and 7.44±0.02 (N=5, NMR spectroscopy) when the muscles were incubated in aerated seawater medium at pH 7.65 in the absence of serotonin. The value of pH i estimated with DMO was significantly lower than that estimated by NMR. Nevertheless, results from both methods can be considered to show good agreement because a difference of 0.03 pH units is low.

During the active phase of a tonic contraction under isotonic conditions, pH i rapidly and significantly increased from 7.44±0.02 to 7.54±0.01 (N=5, NMR). This alkalosis can probably be correlated with a breakdown of the phosphagen phospho-$\gamma$-arginine, by which ABRMs support most of their energy demand during the working phase of contraction (Nauss and Davies, 1966; Zange et al. 1989). The splitting of a phosphagen generally causes consumption of protons because the pK value of the phosphate group in the phosphagen is higher than that of inorganic phosphate (Pörtner, 1987).

When catch was elicited by the removal of acetylcholine, pH i returned to resting levels within 3 min. This fast readcification could be correlated with the resynthesis of phospho-$\gamma$-arginine (Nauss and Davies, 1966; Zange et al. 1989).

Contractile filaments of the living ABRMs maintain tension and shortening during catch at a pH i of 7.44. When skinned fibres of the ABRM were incubated at this physiological pH, however, they failed to enter the catch-like state which can be elicited by the removal of Ca$^{2+}$ after an active contraction. Therefore, studies on the catch-like state of skinned fibres have been performed using acidic media.
between pH 6.2 and 6.8 (Johnson, 1959; Ruegg, 1971; Ishii, 1987). Pfitzer and Ruegg (1982) found striking similarities between the mechanical behaviour of living ABRMs during catch and skinned fibres of the ABRM during the catch-like state at pH 6.5. For the time being we cannot resolve this discrepancy of the functional involvement of pH in catch in living ABRMs compared with skinned fibres.

In the skinned fibre experiments mentioned above, the incubation medium contained about 150 mmol L⁻¹ Cl⁻. In their study on skinned axonemes from sea urchin sperm, Gibbons et al. (1985) have shown that the activity of the dynein ATPase depends on the concentration of Cl⁻ in the medium, the enzyme being 1.5 times more active at a concentration of 150 mmol L⁻¹ than in the presence of 30 mmol L⁻¹ KCl. Using organic anions to make up the same ionic strength had no effect. Gibbons et al. (1985) showed that the relative concentration of Cl⁻ and organic anions in the incubation medium could affect some contractile systems and therefore must be taken into account. Future research must also ensure that catch in the living ABRMs and catch in skinned fibres are based on the same molecular mechanism.

In intact ABRMs, both alkalinization elicited by methylamine and acidification caused by unlabelled DMO induced changes in stretch resistance of the ABRM during catch. Methylamine was used because the membrane permeability of methylamine is known to be slightly lower than that of DMO (Boron and Roos, 1976). Therefore, changes in pH induced by methylamine could be monitored by the distribution of DMO. Catch was examined by the rate at which an ABRM loaded with 0.1 N was stretched (Vₚ). When pH increased to 7.54±0.05 (N=8, DMO method), the relaxation rate was increased from 0.05±0.03 to 0.16±0.04 mm min⁻¹ (3.2 times). A further rise in pH to 7.61±0.07 increased the rate of relaxation 18-fold. Acidification (pH 7.28±0.04) diminished the relaxation rate by 56%. Previous assumptions, drawn from skinned fibre experiments, that the maintenance of catch by a living ABRM depends on pH (Johnson, 1959; Ruegg, 1971), have therefore been confirmed in this study. It should, however, be kept in mind that the pH-sensitive range of catch in living ABRMs is about 0.6–1.2 pH units above that of skinned fibres.

Serotonin (10⁻⁵ mol L⁻¹) induced a rapid relaxation of the ABRM, an increase in cyclic AMP levels from 3.2 to 38.9 nmol g⁻¹ and a slow increase of pH which reached its maximum of 7.57±0.02 (N=5, NMR method; 7.56±0.05, DMO method) after 15 min. Serotonin also induced an alkalinization in resting muscles. pH remained at the higher level as long as serotonin was present. Alkalinization, which was also elicited by the combined effect of forskolin and IBMX or by 8-bromo-cyclic AMP, proves that cyclic AMP acts as a second messenger of serotonin in terms of a modulation of pH. The dose–response curves of serotonin show that a minimum concentration of 10⁻⁶ mol L⁻¹ is necessary to induce significant effects on both cyclic AMP levels (Köehler and Lindl, 1980) and pH (see Fig. 3). Much lower concentrations of serotonin (10⁻⁹ mol L⁻¹) induce significant effects on the maintenance of catch in living ABRMs (Twarog, 1954).
Application of cyclic AMP abolishes the catch-like state of skinned fibres (Cornelius, 1982; Pfitzer and Ruthig, 1982). If the release of catch in vivo depends on cyclic AMP, applications of either serotonin or 8-bromo-cyclic AMP to living muscles should have similar effects on catch. 8-bromo-cyclic AMP (5 mmol l⁻¹) induced an acceleration of Vₛ from 0.05±0.02 to 0.18±0.09 mm min⁻¹ (N=7). Serotonin, however, induced a significantly faster rate of relaxation than 8-bromo-cyclic AMP (5.0±1.8 mm min⁻¹, 28 times). Striking similarities between the effects of 8-bromo-cyclic AMP and alkalinization elicited by 10 mmol l⁻¹ methylamine (see Fig. 1 and Table 3) suggest that the effect of 8-bromo-cyclic AMP on catch was elicited indirectly by an increase in pHᵢ.

Application of dopamine (10⁻⁵ mol l⁻¹), another catch-releasing transmitter (Twarog and Cole, 1972), did not result in a significant increase of cyclic AMP levels (see Table 2; Ishikawa et al. 1981) or pHᵢ (see Table 2). Electrical stimulation of an ABRM with rectangular pulses (Winton, 1937) during a tonic contraction abolished catch but did not increase cyclic AMP levels (see Table 2).

The application of serotomin may, therefore, activate two mechanisms that are triggered separately in vivo. A more serotonin-sensitive (10⁻⁹ mol l⁻¹; Twarog, 1954) mechanism causes the rapid relaxation of an ABRM during catch. Another, less serotonin-sensitive (10⁻⁶ mol l⁻¹) cyclic-AMP-dependent mechanism causes a rise in pHᵢ, increasing the relaxation velocity of the ABRM during catch.

The dual effect of serotonin, triggered by different receptors, includes the involvement of further intracellular messengers. Serotonin (>10⁻⁵ mol l⁻¹) induces the release of Ca²⁺ from intracellular stores (Bloomquist and Curtis, 1975a,b). As the concentration of free Ca²⁺ remains constant after application of serotonin (Ishii et al. 1989), extrusion of Ca²⁺ from the intracellular space might be coupled with an equimolar release of Ca²⁺ from the contractile filaments, thus releasing catch. As serotonin does not affect the membrane potential (Hidaka et al. 1967), these Ca²⁺ movements might be triggered by an inositol lipid response (Berridge, 1989). The validity of these assumptions should be examined in the future.

We thank Professors Gerd Gade and Rolf Kinne for stimulating discussions and Mr B. Griel for technical assistance. This work was supported by the Deutsche Forschungsgemeinschaft (Gr 456/9-4) and Fonds der Chemischen Industrie (MKG).
