#### Abstract

Due to climate change, the Arctic is warming twice as fast as the rest of the world. This leads to a northward expansion of species from the Atlantic to the Arctic. As a result, the species composition in the Arctic is changing. The Northeast Arctic cod (NEAC) is the most abundant cod population, with a distribution area in the Barents Sea and also in Svalbard. However, NEAC can also be found along the coast of Norway. There the NEAC spawns in the Lofoten region with the Norwegian Coastal cod (NCC), which in turn occurs along the Norwegian coast and in fjords. The offspring is drifted to Svalbard by the prevailing currents. The aim of this work was to investigate the composition of the cod population in Svalbard and whether a local coastal population has formed in Svalbard. For this purpose, the Pantophysin I locus (Pan I) was used to investigate to which ecotype of cod the caught animals from expeditions between August and October in 2018 and 2020 could be assigned. The analysis of Pan I in the caught cod shows that NCC inhabits both coastal and fjord areas in Svalbard. The discovery of NCC in Svalbard is an indication that due to climate change a coastal population may become established in Svalbard, with effects on the prevailing ecosystem in Svalbard.

## 1 Introduction

Due to climate change, the Arctic has warmed at nearly twice the rate as the rest of the world over the last decades (NSIDC, 2020). The Svalbard archipelago, the sampling area of this thesis, is also affected by climate change and its consequences. Svalbard is influenced by cold and warm water masses of different origins. The east coast of Svalbard is influenced by cold water from the Arctic Ocean moving southwards (Spotowitz et al., 2022). The west coast of Svalbard, on the other hand, is influenced by warmer Atlantic currents. The West Spitsbergen Current (WSC), which is a branch of the gulf stream, moves northwards along the west coast (Spotowitz et al., 2022). Thus, in the region around Svalbard, Atlantic water, which is steadily warming, enters the Arctic Ocean (Onarheim et al., 2014). This increased warming will lead to changes that may affect Arctic food webs and the well-being of Arctic communities (Vincent, 2020). Due to the warming of the Arctic waters the sea ice cover is declining, opening new habitats. Since 1979, the trend in winter ice area loss is close to $10 \%$ per decade (Onarheim et al., 2014). A northward expansion of invasive species from the Atlantic, such as Atlantic cod (Gadus morbua (Linnaeus, 1758)), is a consequence of warming (Renaud et al., 2011; Mark et al., 2014), causing a change in species distribution and occurrence in the Arctic (Spotowitz et al., 2022).
G. morbua is a bentho-pelagic fish and distributed in the boreal regions of the North Atlantic and the Arctic (Drinkwater, F., 2005) (Figure 1).

Figure 1: Distribution of Atlantic cod.
The area of distribution is shown in grey. Spawning areas are shown in dark grey. (Drinkwater, 2005).

In the North Atlantic, more precisely in the Barents Sea and in the waters along to the coast of Norway, exist two main groups of Atlantic cod. The Northeast Arctic cod (NEAC) and the Norwegian Coastal cod (NCC). Both belong to the species Gadus morbua. The two cod populations differ in their way of life. The NCC is more stationary along the coast of the North of Norway and is found inside fjords. The NCC spawn their eggs in different locations along the coast and inside fords in springtime (Dahle et al., 2018; Fevolden et al., 2009). The main spawning period is from March to April (Nordeide et al., 1998). The eggs drift passively with the Norwegian Coastal Current from the spawning sites in the North of Norway to the Barents Sea until they finally are able to reach Svalbard. Now it may happen that, due to consequences of climatic changes such as the decline of sea ice, the offspring of the NCC can survive the winters in ice-free areas of fords and, as they show less migratory behaviour (Stransky et al., 2008), they settle as a local population in the fjords and the west coast of Svalbard. Nevertheless, the NCC undertakes local coastal migrations (Berg \& Albert, 2003). In contrast, the NEAC is a migratory species. They have their feeding area mainly in the Barents Sea but also along western Svalbard (Otterå et al., 2020, Andrade et al., 2020). However, its spawning area is in the North of the Norwegian coast in the region of Lofoten and Vesterålen whereto the adults of NEAC migrates between December and January (Otterå et al., 2020; Sarvas \& Fevolden, 2005; Andersen et al., 2015). The offspring drift with the Norwegian Coastal Current from the coast of Norway to the northeast and mix with the Atlantic water until finally reaching the Barents Sea and Svalbard (Vikebø et al., 2005). The migratory ecotype of Atlantic cod such as the NEAC comprise the largest known cod stock compared to the NCC as a stationary population (Spotowitz et al., 2022; Markusson, H., 2020). Atlantic cod in Svalbard waters are generally assigned to the ecotype of NEAC according to the literature (Spotowitz et al., 2022). Accordingly, the spawning sites of NEAC and NCC overlap around the Lofoten during springtime (Dahle et al., 2018; Fevolden et al., 2012; Spotowitz et al., 2022; Nordeide et al., 1998). This temporary geographical overlap around the Lofoten can lead to interbreeding of the two populations and the emergence of hybrids (Stransky et al., 2008). Therefore, hybrids originate in the Lofoten region and not in Svalbard, as the NEAC has their spawning sites around the Lofoten and not in Svalbard.

As already mentioned, eggs and larvae are drifted northwards from the spawning sites in the North of Norway with the Norwegian Coastal Current finally reaching Svalbard. This also affects offspring of the NCC. There is growing evidence that a cod ecotype (NCC) that is now able to establish itself in the fjords of Svalbard due to warming will compete with native species for habitat and food, leading to a change in species composition and thus changes in the local Arctic ecosystem. Furthermore, it has already been described that cod attributed to the NCC ecotype have
also been caught in fjords on the west coast of Svalbard (Andrade et al., 2020). The interest here is whether NCC has settled permanently in Svalbard or whether this population is only temporarily resident in Svalbard (Andrade et al., 2020). Therefore, this thesis aims to investigate the population composition of Atlantic cod surveyed in Svalbard waters in 2018 as well as 2020 and whether the NCC has already established itself as a stationary coastal cod population in Svalbard due to the described consequences of climate warming. Due to the rising temperatures, there is the potential that they can survive the winter and settle in Svalbard. This could lead to perennial stocks forming and reproducing in the new habitat. The questions which emerge are: 1.) will a representative number of NCC individuals be found among the selected samples and are they already of reproductive age? It has been reported that coastal cod become mature at the age between 5 and 6 years in average (Berg \& Albert, 2003). The ability of reproduce can therefore be inferred from the age. The age, in turn, can be determined by the length of the animals. Knowing that the NCC tends to be more stationary, the size of the individuals might indicate the length of stay in the respective locality. 2.) are the available data sufficient to support the statement that a costal stock of Atlantic cod (NCC) has become established at the respective locations and remains there throughout the year?

These hypotheses were tested by differentiating the selected samples, taking advantage of a specific gene locus identified in Atlantic cod in the 1990s, Pan I (Fevolden and Pogson, 1997). The gene locus (originally called GM798) codes for an integral membrane protein (Pogson, G. H., 2001), which can serve as a genetic marker for characterisation Atlantic cod ecotypes by using allelespecific PCR in combination with a subsequent fragment length analyse (Stenvik et al., 2006). Pan I encodes part of the protein pantophysin, which is a cellular isoform of synaptophysin and occurs in neuroendocrine as well as in non-neuroendocrine tissues (Haass et al., 1996). The protein consists of four transmembrane domains, two intravesicular loops and two cytoplasmic tails (Pogson, G. H., 2001). Pan I of the Atlantic cod shows genetic differences between stationary (NCC) and migratory (NEAC) populations (Andersen et al., 2015). This allows us to determine the ecotype by genotyping the selected samples. The gene Pan I is biallelic and can be found in three different variants (Otterå et al., 2020). Figure 2 describes the three different variants in which the Pan I alleles can be present. One possible allele variant is Pan I ${ }^{\text {AA }}$ (blue) which shows the homozygous genotype of the Pan $\mathrm{I}^{\mathrm{A}}$ allele dominating in the relatively stationary Norwegian Coastal cod (NCC). Variant 2, Pan $\mathrm{I}^{\mathrm{BB}}$ (red), represents the homozygous genotype of the Pan $\mathrm{I}^{\mathrm{B}}$ allele which is predominant in the migratory population of the Northeast Arctic cod (NEAC) (Felvolden \& Pogson, 1997; Andersen et al., 2015). And the third variant, Pan I ${ }^{\mathrm{AB}}$, shows the heterozygous form with both alleles A and B are present, indicating the hybrid form. The different
intensities also become clear. For Pan $\mathrm{I}^{\mathrm{AA}}$ and $\operatorname{Pan} \mathrm{I}^{\mathrm{BB}}$, the intensities are clearly higher compared to the standard (orange). For Pan I ${ }^{\mathrm{AB}}$, both allele peaks have almost the same intensity.

Figure 2: Pan I Genotyping.
The three different genotypes of Pan I of the Atlantic cod after fluorescent allele-specific PCR and genotyping. (Stenvik et al., 2006).

## 2 Material and Methods

For genotyping cod using the Pan I locus DNA is extracted, which is the DNA template for the subsequent PCR, amplifying the Pan I locus. This is done with the help of specific fluorescentlabelled reverse primers and an unmodified forward primer, flanking the region of the sequence to be amplified and serving as a starting point for the DNA polymerase. The length of these synthesised DNA fragments is then determined by fragment length analysis, which allows conclusions to be drawn about the ecotype.

### 2.2 Sampling area

The sampled G. morbua for the analysis of this thesis come from two different cruises carried out in the past years: in 2018 (cruise code: HE519) and 2020 (HE560), the cruises organized by the Alfred-Wegener-Institute (AWI) with the research vessel Heincke took place in the water around Svalbard and in its fjords. A total of 12 stations were sampled, with a total of 317 individuals surveyed (7.1.1, see appendix). The fish were partly caught by angling, but also caught with pelagic and bottom trawl. From the caught fish, among other things, muscle tissue (stored at $-80^{\circ} \mathrm{C}$ ) as well as finclips (stored in ethanol at $-20^{\circ} \mathrm{C}$ ) were taken. For this thesis, stations within fords as well as stations from coastal and fjord areas were selected. From all stations of both cruises, a total of 7 were selected (Figure 3, Figure 4, Table 5, Table 6).

Figure 3: Selected Stations of HE519 in 2018.
Selected Stations (yellow) for this thesis of the cruise to Svalbard with Heincke (HE519) in the year 2018: S001 Bear Island, S002 Hornsund, S003 Moffen, S004/S005 Raudfjorden, S008 Kongsfjorden.

All individuals from these stations were sorted in ascending order of total length (TL) for each station to assign them to a size class (7.1.2, see appendix). 12 different size classes were defined. Size class 1 was assigned to individuals with total lengths between 0 and 9.9 cm , size class 2 to 10.0 to 19.9 cm etc. up to size class 12 with 110.0 to 119.9 cm total length (Figure 5). Finally, 10 individuals per station were chosen (Table A 1, see appendix). The smallest and the largest individual were selected, as well as animals in size classes in between, so that individuals of different sizes could be used for the analysis (Figure 6).

All individuals ( $\mathrm{n}=50$ ) of YMP/SMB assigned to size classes

### 2.3 Purification of DNA

### 2.3.1 DNA Extraction

DNA was extracted using a DNeasy Blood \& Tissue Kit (QIAGEN). An adjusted Quick-Start protocol (April 2016) was used.
The first step of the DNA extraction was to lyse the samples with help of proteinase K.
For this step, a 1.5 ml tube (Eppendorf) was prepared with $180 \mu \mathrm{l}$ ATL buffer and $20 \mu \mathrm{l}$ proteinase K for each sample. These were mixed by vortexing and they were then centrifuged quickly. The samples were taken under sterile conditions. For this purpose, two forceps were cleaned with $70 \%$ ethanol and then flamed with the aid of a Bunsen burner. This procedure was repeated after each sample to avoid contamination. Furthermore, a petri dish was needed for the finclips, which were also thoroughly cleaned with ethanol after each sampling.
For finclips (stored in ethanol at $-20^{\circ} \mathrm{C}$ ), attention was paid to ensure that only tissue from lower skin layers was collected to avoid possible contamination from skin surface. Therefore, the top layer of skin was lifted off and the exposed tissue was used for the extraction. Before finclip samples were transferred into the prepared lysis solution, they were carefully blotted out on a KIMTECH cloth after collection so that no ethanol remained on the tissue. Muscle samples (stored at $-80^{\circ} \mathrm{C}$ ) were transferred directly from the storage-tube into the prepared tubes with the lysis solution. The samples were then incubated at $56^{\circ} \mathrm{C}$ and 450 rpm overnight.

After incubation, the lysate was briefly mixed and centrifuged. In the next step, the DNA is selectively bound to the membrane of the DNeasy Mini spin column. For this, $200 \mu \mathrm{l}$ Buffer AL was premixed with $200 \mu$ l ethanol per sample. $400 \mu$ l of the premix was added to the lysate and immediately mixed thoroughly to homogenise. The whole mixture was pipetted onto the DNeasy Mini spin column and centrifuge at $6000 \mathrm{xg}(6.0 \mathrm{rcf})$ for 1 min . During the centrifugation, the DNA is bound to the membrane as contaminants pass through (DNeasy Blood and Tissue Handbook, QIAGEN, S.9). The flow-through and the collection tube were discarded, and the spin column was placed in a new 2 ml collection tube. In the following two wash steps, the remaining contaminations were removed. $500 \mu \mathrm{l}$ Buffer AW1 was added onto the spin column and centrifuge at $6000 \mathrm{xg}(6.0 \mathrm{rcf})$ for 1 min . The throw-through and the collection tube were discarded. The spin column was placed in a new 2 ml collection tube. $500 \mu \mathrm{l}$ Buffer AW2 was added onto the spin column and centrifuge at $16.100 \mathrm{xg}(16.1 \mathrm{rcf})$ for 3 min . The collection tube was emptied and blotted, then the spin column was placed back onto the collection tube and centrifuge again at 16.100 xg ( 16.1 rcf ) for 1 min . The collection tube including flow-through was discarded and the spin column was transferred to a new 1.5 ml microcentrifuge tube. To elute the DNA from the membrane of the DNeasy Mini spin column, $150 \mu$ Buffer AE was pipetted to the center of the
spin column membrane and incubate at room temperature for 1 min . After incubation, centrifuged at $6000 \mathrm{xg}(6.0 \mathrm{rcf})$ for 1 min . The spin column was discarded. The DNA is eluted in the buffer.

### 2.3.2 Quantification of the purified DNA

To determine the yield of the extracted DNA the concentration was measured a Nanodrop Spectrophotometer. The absorbance peak of DNA is at 260 nm , that of proteins at 280 nm . The ratio of absorbance at 260 and 280 nm provides information about the purity of the measured DNA. DNA is considered pure when the ratio is $\sim 1,8$. If the ratio is clearly below 1,8 , this may indicate contamination, for example by protein.
So that the measurement of the DNA concentration is not falsified by the absorbance values of the buffer, a previous reference measure is necessary, which is carried out with buffer AE in which the DNA is eluted. After blanking, the DNA concentration ( $\mathrm{ng} / \mu \mathrm{l}$ ) of all samples was quantified (Table A 2, see appendix). The purified DNA samples were then diluted in distilled water to an end concentration of $10 \mathrm{ng} / \mu \mathrm{l}$ with a final volume of $50 \mu \mathrm{l}$. For this purpose, the following formulas were used:

To determine the needed volume of the eluted DNA:

$$
v_{1}=\frac{c_{2}(\text { end concentration }) * v_{2}(\text { endvolume })}{c_{1}(\text { concentration of the purified } D N A)}
$$

To determine the needed volume of $\mathrm{H}_{2} \mathrm{O}$ :

$$
v_{H 2 O}=v_{2}-v_{1}
$$

The pure DNA as well as the diluted DNA were immediately stored at $-20^{\circ} \mathrm{C}$.

### 2.4 Allele-specific Polymerase Chain Reaction

By using PCR, specific DNA sequences can be amplified in vitro (Sadava et al., 2006). PCR was performed to amplify the Pan I locus and to identify in a subsequent fragment analysis, if one or both alleles of the locus are present. For this purpose, two different fluorescent-labelled reverse primers, specific for Pan $I^{A}$ (PanIAfam-R) or Pan $I^{B}($ PanIBhex-R), and one unlabelled forward primer (PanI-2-PIG), flanking the searched locus and serving as a starting point for the polymerase, were used (Table 7). The fluorescent primers allow a specific amplification of the Pan I locus in PCR (Stenvik et al., 2006). The forward primer was modified by a PIG-tail. This means that a sequence is added to the 5'end, in our case the sequence GTTTCTT (Table 7). The PIG-tailing modification is intended to improve the genotyping (Brownstein et al., 1996).

Table 7: PCR primer list.
Primers with their respective sequences and band sizes. PIG-tail sequence underlined.

| Primer name | Sequence (5'-> 3') | Band size in Bp |
| :--- | :--- | :---: |
| PanI-2-PIG | GTTTCTTTGACAGCGCTTGGCAAATGAA | 28 |
| PanIAfam-R | GCTTAAGCAGATATCGCAGTAGTTTC | 26 |
| PanIBhex-R | TTAAGCAGATCTCCGCAGTAGTTTT | 24 |

The final volume of the PCR mix was $20 \mu \mathrm{l}$ per sample consisting of $18,5 \mu \mathrm{l}$ PCR reaction mix and $1,5 \mu$ template DNA. The total volume was determined according to the number of samples. All volumes of the required components were determined according to the supplier's information (Table 8) in relation to the calculated total volume for the reaction mix. The amount of water was determined proportionally from the sum of these. Two PCR reaction mixtures were prepared, each with one of the two primers since it was decided against a multiplex PCR during the pretests. Starting with water, all components were pipetted in order 1-6 (Table 8) into a reaction tube and mixed by vortexing. Finally, PCR reaction tubes were prepared with $18,5 \mu$ of the reaction mix and $1,5 \mu \mathrm{l}$ of the template DNA.

Table 8: Pipetting instructions.

| Order | Component | Stock <br> concentration | Final <br> concentration |
| :--- | :--- | :---: | :---: |
| 1 | Phire Reaction Buffer | 5 X | 1 X |
| 2 | dNTPs | 2 mM | $0,2 \mathrm{mM}$ |
| 3 | Primer fwd | $100 \mu \mathrm{M}$ | $0,5 \mu \mathrm{M}$ |
| 4 | Primer rev | $100 \mu \mathrm{M}$ | $0,5 \mu \mathrm{M}$ |
| 5 | DMSO | - | $0,6 \mu \mathrm{l} /$ reaction |
| 6 | Phire Hot Start II DNA Polymerase | - | $0,4 \mu \mathrm{l} /$ reaction |

A Mastercycler was used for the Polymerase Chain Reaction. After an initial denaturation step for 30 sec at $98^{\circ} \mathrm{C}, 30$ cycles of DNA amplification followed. The DNA is heated to $98^{\circ} \mathrm{C}$ for 5 sec , whereby the single strands separate. The denaturation is followed by primer annealing at $64^{\circ} \mathrm{C}$ for 5 sec . In this step, the primers bind to their target sequence (Sadava et al., 2006). In the following extension step with a temperature of $72^{\circ} \mathrm{C}$ for 10 sec the DNA polymerase synthesizes the new complementary strands, using the dNTPs as building blocks (Sadava et al., 2006). Once the 30 cycles are completed, the process ends with the final extension at $72^{\circ} \mathrm{C}$ for 1 min and the subsequent final hold at $4^{\circ} \mathrm{C}$. During the reaction, the buffer regulates the pH value (Sadava et al., 2006) to guarantee optimal conditions for the activity and stability of the DNA-polymerase (Gelfand, 1989).

### 2.5 Gel electrophoresis

To verify whether the PCR worked, which means the primer successfully bind to their target region, a gel electrophoresis was run. According to the literature, the size of the products determined by fragment analysis is 79 bp for Pan $\mathrm{I}^{\mathrm{A}}$ und 77 bp for Pan $\mathrm{I}^{\mathrm{B}}$, so a band just above the 50 bp band of the DNA ladder should be visible in our gel.
A 3\% (weight/volume) Agarose gel was produced by dissolving 3 g Agarose in 100 ml TAE (Tris-acetate-EDTA) buffer. The mixture was heated up until a homogeneous solution was obtained. When the solution was cooled down, it was poured to a gel tray equipped with gel combs. After polymerisation of the solution, the gel tray was transferred into the electrophoresis chamber filled with TAE-buffer. Afterwards the gel combs were removed so that the gel was ready for sample application. To prepare the PCR products for the gel electrophoresis, $1 \mu \mathrm{l}$ DNA Loading Dye was placed into a reaction plate and $4 \mu \mathrm{PCR}$ product was added.

All samples were pipetted into the lanes and finally $3 \mu \mathrm{l}$ of the DNA ladder was applied. The electrophoresis chamber was connected to a power supply and the gel run for 35 min at 100 V . For visualisation of the gel a transilluminator was used. The gel was placed into a staining solution to make the DNA fragments visible in form of bands by UV light.

### 2.6 DNA Fragment length analysis

### 2.6.1 Capillary electrophoresis using Genetic Analyser 3130xl (Applied biosystems)

By using fragment analysis, the size of fluorescent-labelled DNA fragments can be determined. The fragments are separated by capillary electrophoresis, whose capillaries are filled with polymer, and detected by laser, whereby the exact size in bp is determined by comparison with a size standard. This genetic analysis method was used to find out in the subsequent evaluation whether the allele exists homozygous or heterozygous, which then allowed us to determine the ecotype. To prepare the PCR products for the fragment length analysis, they were first diluted 1:20 in distilled water. Then a mixture of $15 \mu \mathrm{l}$ per sample of HiDi and $0,3 \mu \mathrm{l}$ per sample of ROX size standard was prepared. Afterwards, $15 \mu \mathrm{l}$ of the HiDi-ROX-mix and $1 \mu \mathrm{l}$ of the diluted PCR product were pipetted into a 96 -well plate and directly denatured at $95^{\circ} \mathrm{C}$ for 5 min . Before the plate was placed into the Genetic Analyser, it was cooled in a cooling rack. One run for 16 samples took 90 min .

### 2.6.2 GeneMapper Software

If the labeled primer has bound to the target region of the DNA during PCR and the respective products synthesized, the labelled products could then be detected by the laser of the Genetic Analyser. The GeneMapper Software was then used to illustrate and analyse the results. To be able to analyse the products, a new analysis method was created as described in the manual of the GeneMapper Software (Thermo Fisher Scientific, 2009). The allele and marker definitions including the fragment size (bp) and the dye colour for both were defined and adjusted.

The size standard ROX75 indicates a peak at a length of 75 bp . It represents a reference point to which the peaks of the labelled Pan I allele sequences are related. On the one hand, this allows the length (bp) of the products to be inferred. On the other hand, the relation between the intensity or height of the standard peak and that of the products can be used to determine whether the allele is homozygous or heterozygous, as described above.

Accordingly, the important information was the intensity of the Peak (height in datapoints) and the length of the fragment (bp). Based on these data, conclusions could be drawn in which variants the alleles were present. Therefore, a sizing table was created, which displays a row of sizing information for each detected peak (Applied Biosystems, 2009). The data of the height of the peak and the base pair length of the labelled products were taken from the sizing table of the Gene Mapper Software. An Excel table was created based on this sizing table (7.1.3, see appendix).

### 2.7 Correction of the raw data

As already described, the value of ROX75 intensity is the reference point to which the intensities of the allele peaks are referred. This means that the intensities of the allele peaks are considered in relation to the intensity of ROX75. It is therefore important that ROX75 has the same value in all samples so that the allele intensities linked to the standard by the ratio can be compared with each other. Since the two primers for the Pan I alleles were used separately in the PCR, two fragment analysis results were available for each sample in which ROX75 did not always have the same intensity value. This also occurred when the results of the intensities of the different samples were compared with each other. Therefore, it was necessary to adjust the data using correction factors for comparability.

### 2.7.1 Correction of the intensity values

In order to firstly compare the data for each sample of the identical DNA and secondly that all samples can be compared with each other, the intensity value of ROX75 was set to the value 500 for all samples. Thus, the measured intensity values of the alleles also had to be adjusted to the newly determined ROX75 value (ROX75 corr) so that the ratio of intensity between ROX75 and the alleles is maintained. In the following, this new value of the ratio is called 'correction factor' ( corrf $_{\mathrm{f}}$ ).

The fragment analysis results of sample GmoH 025 were used for the following calculation example:

Results of GmoH025 for Pan I ${ }^{\Lambda}$ :
Table 9: Results of the fragment length analysis for $\mathbf{G m o H} 025$ for allele Pan $\mathrm{I}^{\mathrm{A}}$.

| Intensity of the ROX75 (in dp) | Intensity of the Pan $\mathbf{I}^{\text {A }}$ (in dp) |
| :---: | :---: |
| 844 | 642 |

First, the ratio of the $\mathrm{ROX}_{\text {corr }}$ value of 500 dp to the measured value of $\operatorname{Pan} \mathrm{I}^{A}$ was calculated:

Definition of corrr $_{f}$ for Pan I ${ }^{A}$ :

$$
\operatorname{corr}_{f}\left(\text { Pan }^{A}\right)=\frac{R 0 X 75_{\text {corr }}}{\text { Pan I }^{A} \text { intensity }}
$$

Calculation of $\operatorname{corr}_{f}\left(\operatorname{Pan~I}^{A}\right)$ :

$$
\operatorname{corr}_{f}\left(\operatorname{Pan}^{A}\right)=\frac{500}{844}=0,59241706
$$

Next, the $\operatorname{corr}_{f}\left(\operatorname{Pan~}^{A}\right)$ was applied to the measured value of Pan $I^{A}$ allele intensity to determine the new intensity (Pan I ${ }^{A}$ corr) relative to the ROX75 corr intensity value of 500 dp , so that the ratio of the two values remains the same even though the ROX75 value is new.

For this purpose, the following calculation was used:

Definition of Pan I ${ }^{A}$ corr:

$$
\text { Pan } I^{A} \operatorname{corr}=\operatorname{corr}_{f}\left(\operatorname{Pan} I^{A}\right) \times{\operatorname{Pan} I^{A} \text { intensity }}^{2}
$$

Calculation of Pan I ${ }^{A}$ corr:

$$
\text { Pan } I^{A} \text { corr }=0,59241706 \times 642=380,331754
$$

Results of GmoH025 for Pan $\mathrm{I}^{\mathrm{B}}$ :
Table 10: Results of the fragment length analysis for GmoH 025 for allele Pan $\mathrm{I}^{\mathrm{B}}$.

| Intensity of the ROX75 (in dp) | Intensity of the $\operatorname{Pan~}^{\mathbf{I}^{\mathrm{B}}}$ (in dp) |
| :---: | :---: |
| 675 | 1139 |

Definition of corr ${ }_{f}$ for Pan $I^{B}$ :

$$
\operatorname{corr}_{f}\left(\text { Pan }^{B}\right)=\frac{R O X 75_{\text {corr }}}{{\text { Pan } I^{B} \text { intensity }}^{\text {in }}}
$$

Calculation of $\operatorname{corr}_{\mathrm{f}}\left(\operatorname{Pan~I}^{\mathrm{B}}\right)$ :

$$
\operatorname{corr}_{f}\left(\operatorname{Pan}^{B}\right)=\frac{500}{675}=0,74074074
$$

Definition of Pan I ${ }^{\mathrm{B}}$ corr:

$$
\text { Pan } I^{B} \operatorname{corr}=\operatorname{corr}_{f}\left(\operatorname{Pan} I^{B}\right) \times \operatorname{Pan} I^{B} \text { intensity }
$$

Calculation of Pan I ${ }^{\mathrm{B}}$ corr:

$$
\text { Pan }^{B} \text { corr }=0,74074074 \times 1139=843,703704
$$

The data of Pan I ${ }^{A}$ corr and Pan $I^{\mathrm{B}}$ corr obtained in this way were rounded to the nearest integer:

Table 11: New values of ROX75, Pan $\mathrm{I}^{\mathrm{A}}$ and $\mathrm{I}^{\mathrm{B}}$ of GmoH 025.

| Intensity of the ROX75 corr <br> (in dp) | Intensity of the Pan I ${ }^{\mathbf{A}}$ corr <br> (in dp) | Intensity of the Pan $\mathbf{I}^{\mathbf{B}}$ corr <br> (in dp) |
| :---: | :---: | :---: |
| 500 | 380 | 844 |

In this way, the intensity values of all samples were corrected (Table A 3, Table A 4, see appendix).

### 2.7.2 Determination of an identification factor

Since, as already mentioned, heterozygosity or homozygosity is determined, among other things, by comparing the height of the peak (intensity) of the alleles with the standard and the values of the intensities of the two Pan I alleles are already related to the standard as a reference point. The evaluation could be carried out by looking at the ratios of the intensities.

The results of the fragment length analysis of this project, differed from those described in the literature as follows. There were results $(\mathrm{n}=30)$ that showed a single peak and thus allowed a clear ecotype assignment. However, the remaining results $(\mathrm{n}=40)$ deviated from the results in the literature to the effect that even though these samples showed a peak at the location of allele A and a peak at the location of allele B , but the ratios of the two peaks did not clearly point to the third allele variant (heterozygosity). Therefore, an additional calculated factor had to be introduced, which nevertheless allows the deviating results to be interpreted. This is referred to as the "identification factor" (ident $f_{f}$ ) in the following. Ident indicates how much higher or lower the $^{\text {l }}$ intensity of the Pan $I^{A}$ corr allele is compared to the Pan $I^{B}$ corr allele, i.e., the intensity ratio of Pan I ${ }^{A}$ corr : Pan $I^{B}$ corr is.

The following example calculation is intended to illustrate the ident ${ }_{f}$ explained in the previous section. The corrected values of sample GmoH 025 are used for the calculation (see above).

Definition of ident:

$$
\text { ident }_{f}=\frac{\text { Pan I }^{A} \operatorname{corr}}{\text { Pan }^{B} \operatorname{corr}}
$$

Calculation of ident:

$$
\text { ident }_{f}=\frac{380}{844}=0,45
$$

In this way, ident ${ }_{f}$ of all samples were calculated (Table A 5, see appendix).

The ident ${ }_{f}$ could then be used to decide which of the three possibilities of the Pan I genotype was applicable. Ranges were defined for this purpose.

Homozygosity:
Variant 1 Pan $I^{A A}$ : From an ident of 2.0 , the individuals are assigned to the NCC ecotype. This means that from a ratio of the intensity of the Pan $\mathrm{I}^{\mathrm{A}}$ allele to that of the $\operatorname{Pan} \mathrm{I}^{\mathrm{B}}$ allele of 2:1, homozygosity for Pan IA is determined.

Variant 2 Pan $\mathrm{I}^{\mathrm{BB}}$ : An ident of 0.5 or smaller, in other words, if the ratio between the intensity of the Pan $I^{A}$ allele and that of the Pan $I^{B}$ allele is at maximum 1:2, homozygosity for Pan $I^{B}$ is defined thus the individual belongs to the ecotype of the NEAC.

Heterozygosity:
Variant 3 Pan $\mathrm{I}^{\mathrm{AB}}$ : If the calculated ident ${ }_{\mathrm{f}}$ is between 0.51 and 1.99 , the individual is assumed to have a heterozygous genotype and is thus assigned to the group of hybrids.

## 3 Results

### 3.1 Genotype plots

In this project, the genotyping was performed in order to determine the ecotype of the collected samples. The two different fluorescent primers specific for Pan I were detected by the laser of the Genetic Analyser 3130xl. If the allele was present, this was displayed in form of a peak in position of the respective base pair length with 77 bp for Pan $I^{\mathrm{B}}$ and 79 bp for Pan $\mathrm{I}^{\mathrm{A}}$. Fragments from three individuals (GmoH56, GmoH057 and GmoH049) are shown below (Figure 7-9).

### 3.2 Ecotype determination

As already described, the ecotype determination was carried out with the help of the calculated identification factor $\left(\right.$ ident $\left._{f}\right)$. Ident $_{f}$ indicates the ratio of the intensity of the Pan $I^{A}$ allele to that of the Pan I ${ }^{\mathrm{B}}$ allele, both are related to the ROX $75_{\text {corr }}$ Standard. Ranges were determined for the three possible variants of how the alleles can be present. Using this information, it was discovered that of the 70 samples, 24 can be attributed to the ecotype of the NCC (Figure 10, Table 12). 37 individuals belong to the ecotype of the NEAC (Figure 10 ,Table 13) and 9 have both Pan I alleles and are thus hybrids (Figure 10, Table 14).

Figure 10: All tested samples assigned to their ecotype.

### 3.3 Size and age classes of the individuals belonging to Norwegian Coastal cod

As already described, it is assumed that NCC are rather loyal to their location and do not migrate over long distances. In the following, the size classes of the individuals assigned to the ecotype of NCC are presented below. The size will be used to classify the age of the individuals (reference values see Figure 11). This data can be used to make an assumption about how long the animals have already been at the sites and whether a statement can be made about the possibility of the NCCs found being an established local cod population in Svalbard.

Figure 11: Length at age.
"Mean, minimum, and maximum length at age for coastal cod and Nordeast Arctic cod, 1995-2001 combined. [...]" (Berg \& Albert, 2003).

### 3.3.1 Size classes

In this section, the size classes of the three different ecotypes identified are presented for the purpose of completeness. For the discussion of the possible population relocation of the NCC that follows, however, only the presented information on size classes of the NCC (Figure 12A) is used. The length of the smallest individual of NCC is 19 cm , that of the largest 101 cm , on average the length is $71,96 \mathrm{~cm}$. For NEAC the average length is $50,59 \mathrm{~cm}$, the smallest in size class 2 is 13 cm and the length of the largest individual is 110 cm assigned to size class 11 (Figure 12B). Length of the smallest in size class 6 of the hybrid group is 53 cm , the largest is 89 cm . Mean length is $70,22 \mathrm{~cm}$ (Figure 12C).

Figure 12: Size classes of NCC (A), NEAC (B) and Hybrids (C).

| $1(0-9 \mathrm{~cm})$ | $7(60-69 \mathrm{~cm})$ |
| :--- | :--- |
| $2(10-19 \mathrm{~cm})$ | $8(70-79 \mathrm{~cm})$ |
| $3(20-29 \mathrm{~cm})$ | $9(80-89 \mathrm{~cm})$ |
| $4(30-39 \mathrm{~cm})$ | $10(90-99 \mathrm{~cm})$ |
| $5(40-49 \mathrm{~cm})$ | $11(100-109 \mathrm{~cm})$ |
| $6(50-59 \mathrm{~cm})$ | $12(110-119 \mathrm{~cm})$ |

### 3.3.2 Age classes

In this section, the age classes of the three different ecotypes identified are presented for the purpose of completeness. For the interpretation that follows, however, only the presented information on age classes of the NCC is used. The youngest individual of NCC in age class 1 is in the 0 -year group, the oldest $10-11$ years old in age class 10 (Figure 13A). Mean age of NCC is 7 years. The average age of NEAC is between 4 and 5 years. The youngest individuals are in age class 1. The oldest is in age class 11, therefore over 11 years old (Figure 13B). Mean age of the hybrid group is 7 years. Youngest individuals are in age class 5, the oldest in age class 9 (Figure 13C).

B Age classes of individuals assigned to NEAC

Figure 13: Age classes of NCC (A), NEAC (B) and Hybrids (C).

| 3 (3-4 years) | 9 (9-10 years) |
| 4 (4-5 years) | 10 (10-11 years) |
| 5 (5-6 years) | 11 (>11 years) |
| 6 (6-7 years) |  |

### 3.4 Ecotype distribution in relation to locality

In order to make a statement about the locality of the different ecotypes, the results of the determination were assigned to the locations. A differentiation was made between coastal areas and areas within fjords. The differentiation according to the stations selected for this work follows. On this basis of these results concerning the whereabouts, it can be checked with help of ice maps whether the animals found, assigned to ecotype NCC, could have spent the winter at the respective station (Figure A 1-10, see appendix). Based on this, a possible migration behaviour of the NCC could be recognised. The ice maps were selected at maximum ice extent in the area of the station surveyed in the respective year of the cruise (Cryo-Norwegian Meteorological Institute, 2022).

### 3.4.1 Distribution within coastal and fjord areas

Figure 14 shows the distribution of the ecotype of all analysed samples with regard to the areas of the catch locations. Cod were found in both coastal and fjord areas. It was discovered that of 24 individuals of Norwegian Coastal cod, 5 were found inside fords and 19 in coastal areas. Of 37 individuals belonging to Northeast Arctic cod, 22 individuals were located inside fjords and 15 in coastal areas. One hybrid was also found inside a ford and the remaining 8 in coastal areas.

Figure 14: Distribution of Ecotypes.
Ecotype distribution of all analysed samples divided in coastal and fjord areas of Svalbard.

### 3.4.2 Ecotype distribution in regard of the selected stations

Cod were found at all surveyed stations (Figure 15). It is noticeable that on the west coast (stations $000,014)$ most individuals belong to the NCC type of cod. At the two stations in the north of Svalbard $(003,7 B)$ there were more of the NEAC type. At the station near Bear Island, both types of cod are represented equally often. Within the fjords surveyed, most individuals belong to the NEAC ecotype. The group of hybrids is little represented but was found at 6 out of 7 stations.

### 3.4.3 Ice cover

When considering the ice maps, it emerged that no area of the stations surveyed was completely covered by ice in 2018. The area around Moffen (003) in the north of Svalbard was freely accessible without drift ice. In Raudfjorden (004, 005), also in the north, the inner part of the ford was completely covered with ice, but in the front part of the fjord only drift ice was recorded. At the remaining stations on the west coast $(002,008)$, as well as Bear Island $(001)$, only drift ice was recorded.

In 2020, 3 stations in the north of Svalbard were completely covered with ice ( $025,7 \mathrm{~B}, 010$ ). Areas on the west coast of 3 stations $(000,014,015)$ were completely ice-free and drift ice was recorded in the area of the remaining station (020).

## 4 Discussion

The increased warming of the Arctic as consequence of the climate change, may bring a change in Arctic communities. New habitats have opened up due to the decline of sea ice and a northward expansion is possible for species from lower latitudes. One of the species expanding northwards is the Atlantic cod. In this study, it was to investigate whether the Norwegian Coastal cod population can or has established itself in Svalbard. For molecular differentiation of the two cod ecotypes, genotyping using the pantophysin I (Pan I) locus was used.

### 4.1 Biological consideration

The Pan I locus was used to determine to which ecotype the selected samples for this project belong. It was found that Northeast Arctic cod, Norwegian Coastal cod and hybrids were among 70 tested samples. Among those, 37 individuals were assigned to the NEAC population, 24 to NCC and 9 to the hybrid group. As the NEAC begins its spawning migration south between December and January, NEAC was found in Svalbard during the sampling period between August and October in 2018 and 2020. NEAC is the most frequently represented cod type among the samples in this work, accounting for $53 \%$. This result is consistent with data from other studies, which indicate that the NEAC is the largest known cod stock in the north-east Atlantic and the Barents Sea (Spotowitz et al., 2022). After spawning on the Norwegian west coast, the NEAC undertake their feeding migration towards Svalbard after spawning time from April on and thus also reaches the coasts and fjords of Svalbard in summer.

NCC was also found. $34 \%$ of the catch could be assigned to this ecotype. This discovery can be explained by the fact, that the eggs of NCC were passively driven from the spawning grounds in the Lofoten region to Svalbard and due to climate change it can be possible for them to overwinter. The NCC shows less migratory behaviour, only local migrations were attributed to NCC. Therefore, overwintering is dependent on the prevailing conditions on arrival in Svalbard. This study has shown that NCC is present in Svalbard. Accordingly, the offspring must have survived the winter months, if it is assumed that this ecotype is stationary. This means that it is possible for the offspring of NCC to overwinter under the given environmental conditions in Svalbard. The formation of local coastal populations in Svalbard is thus related to the survival during the winter. If the locations of the animals are considered in combination with the ice maps (of the year in which the sampling took place) at maximum ice cover, it can be assumed that there are indeed icefree areas that are habitable for NCC in winter (7.2, see appendix). In addition, assuming that NCC is a non-migratory cod type, it can be assumed that the NCC found have survive the winters in Svalbard according to their age. More precisely, if an individual has reached its seventh year of life, for example, it can be concluded, that is has already spent seven years in Svalbard. Due to the West

Spitsbergen Current bringing warm Atlantic water along the west coast of Svalbard, this area may be suitable for species coming from lower latitudes to live. This effect is further enhanced by the fact that the temperature of the Atlantic water increases by $0.3^{\circ} \mathrm{C}$ per decade (Onarheim et al., 2014). This could be the reason why the most frequent appearance of the NCC ecotype at the surveyed stations is on the west coast of Svalbard. In addition, the west coast remains relatively ice-free in winter except for a little drift ice due to the West Spitsbergen Current, offering the chance of wintering in this area. This appearance of the NCC in Svalbard shows the shift of Atlantic species northwards into Arctic waters, enabled by the changing climatic conditions in the Arctic (Lisa Spotowitz et al., 2022).

In addition to the simple fact that NCC has been found, the individuals have reached sizes that are capable of reproduction. Under the mentioned aspect of location fidelity of the NCC in contrast to the NEAC, which migrates back from its feeding ground to its spawning grounds over a long distance every spring, the adults of the NCC in Svalbard must have already survived there for several years, judging by their size. For this purpose, the sizes (TL [cm]) of the animals were assigned to an age class. The results show that the individuals of the NCC found in this study, ranged in size from 19-101 cm, are between 1-11 years old. The individuals of NCC are on average 7 years old with mean length $71,28 \mathrm{~cm}$. From point of view of site fidelity, it can be assumed that the animals survived an average 7 years in Svalbard. This allows to investigate the question of whether a local cod population has established itself in Svalbard at the respective sites. The forming of a stock that establishes itself in a new location includes, in addition to survival, the ability to reproduce. According to the literature, coastal cod is capable of reproducing between the ages of five and six years old (Berg \& Albert, 2003). Relying on this reference value from the literature, $92 \%$ of the analysed animals (figure 8A) may be capable of reproduction, even though it was not examined if NCC found had already spawned. Nevertheless, the two conditions mentioned above for the establishment of a coastal cod stock in Svalbard would be fulfilled. The stage of maturity of the animals was determined during sampling, all individuals were only in stage 1 or 2 (7.1.1, see appendix). Sampling took place at the end of the summer, i.e., about 5-7 months before spawning season beginning in March. Thus, the gonads had already been formed, but they were still maturing. If the sampling had been conducted in the first quarter of the year, the maturity observations, among others, would have been different. But it is possible that, considering that the animals have reached sizes that are reproductive according to the literature, they have found spawning sites in Svalbard and are reproducing there. Furthermore, tagging experiments on coastal cod have shown that they visit the same spawning grounds every year after making only short local migrations (Berg \& Albert, 2003). Therefore, it is possible that the found reproductive individuals assigned to the NCC ecotype formed a locally migratory coastal population.

Furthermore, it was decided by using ice maps whether it was possible that the animals spent the last winter at the location where they were found (7.2). If the sampled station was covered with ice last winter, the animals in question could not have spent the winter there. This suggests that the animals migrated to the station of interest in the period between the retreat of the ice cover and the sampling. This discovery of local migrations is consistent with results from a study that also described that NCC undertaking local migrations (Andrade et al., 2020). By looking at the ice maps at the times of maximum ice expansion, specific to the respective stations of the catches, it could be determined that at three out of seven stations it had been impossible for the animals to spend the winter at the location found. The reason for that is, that the ice maps show that in Hornsund (025), Moffen (7B) and Raudfjorden (010), the areas were completely covered by ice in spring during the year of the catch (2020). This confirmed it was unlikely that the animals spent the winter at the stations in question and must have migrated to the site of capture after the sea ice had retreated. It was noticeable that the stations were located in the south and on the north coast of Svalbard. The exact route of the animals could not be determined in this work. Most of the individuals stay on the west coast, which is due to the above-mentioned Atlantic influence in this area. It therefore suggests that the NCC feels most comfortable in this area. The results also show that NEAC also reside along the west coast and north of Svalbard. Thus, it can be concluded that both ecotypes essentially follow the currents of the Gulf Stream. It can therefore be assumed that animals found in the north or south of Svalbard most likely migrate northwards and southwards from this area. This is possible in the period after the maximum ice expansion, which is also the period of the catches. However, in order to create a more specific pattern of NCC migration in Svalbard, a more detailed study has to be performed and more samples have to be collected.

### 4.2 Methodological consideration

For this study, however, a self-defined range had to be used, since 30 of the 70 samples did not provide clear results. The results from the fragment length analysis are considered unambiguous if either the Pan I allele is homozygous, meaning that only one of the specific primers for the respective allele has bound and thus only one intensity peak is recorded. This intensity peak is at the 77 bp position for Pan $\mathrm{I}^{\mathrm{BB}}$ or NEAC and at 79 bp for Pan $\mathrm{I}^{\mathrm{AA}}$ or NCC. Or in the case of heterozygosity, both primers have bound, which means that two peaks of the same intensity should be present at the respective bp positions. Among the results for Pan I ${ }^{\text {AA }}$, however, there are 15 samples in which two peaks were detected for both alleles, whereby the intensity for the Pan $\mathrm{I}^{A}$ allele was clearly stronger. The same was the case for the Pan $\mathrm{I}^{\mathrm{B}}$ allele, in which 6 samples were nevertheless classified as homozygous for Pan $I^{\mathrm{B}}$ due to the significantly stronger intensity for the specific primer of the Pan $I^{B}$ allele than for Pan $I^{A}$. In order to be able to assign the ambiguous
samples to a population, ranges ( 0 to $0,5 \operatorname{Pan} \mathrm{I}^{\mathrm{BB}}, 0,51$ to 1,99 Hybrid, off 2,0 Pan $\mathrm{I}^{\mathrm{AA}}$ ) were defined, which allowed a clear classification to the populations. The reasons for the differences in the results compared to those from literature have not yet been conclusively explained. Nevertheless, the results are reproducible because during the phase of optimising the PCR conditions, the same starting DNA was used for different PCR. In the subsequent fragment length analyses, however, the same results were produced for the different PCR products by using identical DNA templates.

## 5 Summary and Outlook

This project investigated whether a local coastal population of NCC ecotype has formed in Svalbard. For this purpose, the population structure in Svalbard waters was studied. The data survey was carried out in September and October 2018, as well as in August 2020 in the coastal and fjord areas of Svalbard. Tissue samples of muscle and fins, as well as other data such as the total length of the fish were measured. Genotyping of cod from results of fragment length analysis (FLA) after previous allele-specific PCR, was performed using the pantophysin I locus (Pan I). The two ecotypes mentioned can be distinguished by their allelic variants of the Pan I locus. NEAC has the homozygous genotype Pan $\mathrm{I}^{\mathrm{BB}}$, whereas NCC is homozygous for the Pan $\mathrm{I}^{\mathrm{A}}$ allele. In addition, there is the heterozygous variant Pan $\mathrm{I}^{\mathrm{AB}}$, which is assigned to the group of hybrids. Due to a discrepancy in the results from the FLA compared to results from the literature, the data had to be adjusted using a correction factor, as well as a calculated identification factor. It has not yet been sufficiently explained where the origin of these differences lies, although it could be verified and confirmed that the identical initial DNA yields the same divergent FLA results. From the usable and reproducible results, it was found that all three ecotypes of cod occur in Svalbard. It was then investigated whether the cod found assigned to the NCC ecotype had reached sizes that were capable of reproduction, which would allow an answer to the question of whether this type has become established in Svalbard. For this purpose, the individuals were divided into age classes based on their sizes using reference values from the literature. This in turn made it possible to determine whether the animals were already able to reproduce. On the basis of these investigations, it could be shown that the NCC found in Svalbard are in age classes that have been able to spawn for several years. On the basis of the fact that these animals show a stationary behaviour and only undertake local coastal migrations, it can be assumed that they have been in Svalbard for several years. In addition, an investigation of migratory behaviour was carried out using ice maps. The ice maps provide information on whether it was possible for the animals to have survived the last winter at the location where they were caught. At stations on the coast (Moffen, 7B), as well as a fjord (Raudfjorden, 010) in the north of Svalbard and a station in a southern fjord (Hornsund, 025), it could be shown that it was not possible for the animals to have spent the winter at these locations. These areas were completely covered by ice. Since the distribution of the animals in Svalbard shows that most individuals of the NCC were found on the Atlantic-influenced west coast, it can be assumed that the animals undertake southward and northward coastal migrations from there. Tagging experiments on the animals in Svalbard would provide more precise conclusions, which, however, could not be carried out within the context of this work. Finally, the appearance of the NCC, which were on average 7 years old, in Svalbard's coasts and fjord areas shows that it is possible for them to have survived there for several years, assuming site fidelity. With more
profound genetic studies, such as single nucleotide polymorphic (SNP) markers, it would be possible to show more specifically whether the population (NCC) in Svalbard is genetically different from that on the west coast of Norway. Which would support the establishment of a Svalbard Coastal cod (SCC) population. Overall, this finding represents a change in species composition in Svalbard, which may have an effect on the already established Arctic inhabitants there. For this, it would be important that Arctic species in Svalbard are also studied annually to show patterns in any changes.

Ebenfalls möchte ich Annegret Müller danken.
 Ein herzliches Dankeschön geht an Dr. Christoph Held.
Danke Andrea für deine tatkräftige Unterstützung und Einarbeitung im Labor, sowie dein immer offenes Ohr! Es hat Spaß gemacht!
Des Weiteren würde ich mich gerne bei Andrea Eschbach bedanken.
unsere Besprechungen, haben mich immer wieder motiviert und mein Interesse an meeresbiologischen Themen verstärkt. Merci!
Danke Dir lieber Felix für deine Unterstützung, dein Verständnis und deinen langen Atem während des gesamten letzten Jahres! Deine Betreuung, sowie
Ein besonderer Dank geht an Dr. Felix Christopher Mark.
